Rural livelihoods and many ancillary industries are dependent on agriculture. Impacts on agriculture sector are multifaceted and raise concerns regarding food safety, food and water security, animal welfare, and environmental protection. Allied agriculture processing industries and sectors such as poultry and dairy are also closely linked. Chemical industries manufacturing pesticides and fertilizers heavily depend on the growth of agroeconomy.

The rural non-farm economy that is seen as a great prospect for livelihood creation is closely linked with agriculture. A large share of rural manufacturing involves production and supply of farm inputs and agroprocessing. Rural services target farmer's needs. Any reduction in farm production will directly impact the rural non-farm sector. Also in India, rural areas are seen as future markets by the manufacturing and the service sector. Good road connectivity and telecommunications have opened up the agricultural markets. Today, rural areas are vibrant markets for the Fast Moving Consumer Goods (FMCG), consumer durables, telecommunication, and financial and insurance services. Any decrease in farm productivity would lead to decreased demand in the otherwise burgeoning Indian manufacturing and service sector.

2.14.4.5 Significance of Local Knowledge and Technologies in Combating Climate Change

People in vulnerable areas, often find simpler ways to adapt themselves to the climate adversities. These innovations are low cost and high potential to upscale. It is important that this knowledge is mined and used to its advantage in similar situation across the country. Some of these innovations would require technical support and refinement before upscaling, while others could be directly shared within communities as best practices. Box 1 illustrates two such cases where communities and individual have gone beyond their limitations and found new ways and manners of combating adversities.

2.14.5 Strategies for Adaptation and Mitigation

2.14.5.1 Increasing Investments in Agriculture Infrastructure

Considering the fact that two-thirds of India's population is dependent upon agriculture, it is important that the sector is made more competitive, efficient, profitable, and less vulnerable. The traditional approach of intensive production and subsidies has to be changed to sustained production and investments. Investments for improving road networks, canal irrigation, power supply, market linkages, improved land, and water management techniques, etc., will help to build resilience and therefore reduce the climate change–related vulnerabilities.

The use of excessive fertilizers and use of technologies for gaining intense production of food crops has resulted in reducing the capacity of soil to provide sustained food production on a long-term basis. The situation is expected to get worse with climate change. Keeping this in view, there is a need for making investments in low risk alternatives, which can help in giving production in a sustained manner. This would include making increased investments in organic agriculture. Promoting organic agriculture will help to conserve the soil nutrients and help to increase the production in a sustained manner. Developing a system of pest control, for reducing the resurgence and migration of pests will stop/reduce losses during production.

2.14.5.2 Developing New Technologies and Innovations

Climate change will impose new challenges for technological innovations to be brought in the agriculture sector. This would include development of new varieties of crops, which can resist the increased trend of warming and increase the productivity without reducing the soil fertility and nutrient content. This would require undertaking research in climate resilient varieties of crops, development of water, and carbon conservation practices. For improving the net output, diversification of crops, increasing opportunities in the allied sectors of farming such as

Box 1

Use of grassroots innovations for reducing vulnerability in agriculture.

Enhancing Production in Varied Situations for Diversified Cropping

The tribal communities residing in the hilly belt of Western Ghats and Dimbhe dam catchment area have devised an innovative method for increasing their agriculture and fish production with support from Shahwat Trust. "About 350–400 ha of land is available for agriculture every year in the submergence area of the Dimbhe reservoir. This land gets submerged in the rising waters of the Dimbhe reservoir when the dam starts to fill up in Jul.–Aug. every year." Shahwat (2008).

After the monsoons, when water from the Dimbhe reservoir is released, the area under submergence having shallow water levels opens up in patches. The tribal people residing near the dam practice drawdown cultivation in these lands. The land remains open for some time and gets submerged when the water table of the dam rises during monsoons. During monsoons, when the water table rises, the same area is used for fishing purpose. The nutrient quality of the soil, in the submergence area is very low. Due to this, the productivity of the crop becomes reduced. The low organic content in water reduces the aquatic productivity and the fish catch during monsoon season. To increase the soil fertility, green manure crops such as Dhencha and Taag were planted. The seeds were sown immediately after the first rains. By the time the seeds grow to about 2–3 ft height in 45–50 days the water table starts increasing. After 1.5–2 months (mid July) water table rises, the leaves of these plants start getting dissolved and decompose forming a green manure. This acts as organic matter for the fish to feed.

The root nodules of this plant allow the growth of nitrogen fixing bacteria in the soil. Due to this, the fertility level of the soil is increased. When the land is again free from submergence it can be put to agricultural production. It was observed that the production levels increased from 3 to 5 quintals.

Increasing Cotton Production in Drought Prone Areas in Jalgaon District in Maharashtra

Local techniques and processes are not only frugal and affordable, but also sustainable (Gupta 2010). The poor often have to live on the edge, and frequently resort to creative ways to combat climate adversities. This is a case of Ms. Pramila and Vikas Shinde who own half hectare land in Pingalwada village of Jalgaon district in Maharashtra.

The area is water scarce and the couple did not have enough financial resources to support a bore well and drip irrigation in their farm. Vikas's wife, Pramila found a new way to optimize the cotton production in her farm. She started growing cotton seeds in plastic bags. Approximately 1 month before the sowing time, she took the bags in the farm and looked after them for 1 month. Pramila kept them in a tree shade in her farm and watered them daily. The seedlings were thus irrigated with limited water. By the time, the monsoons arrive in June, instead of sowing the seeds, Pramila transplanted the grown samplings. While the raw seeds were planted in other farms, grown samplings were transplanted in Pramila's farm. The samplings grew faster and the production increased to 2.5 times. The innovation not only reduced the water requirement for the crop, but also increased its productivity.

livestock, fisheries, horticulture, and other such combinations will help the farmers to earn some extra income and reduce the gap due to economic losses. Since the science of climate change is evolving, the extent of research carried out for understanding the impacts for various agroclimatic regions is limited. Under such situation, the adaptation strategies should focus on providing no regret solutions that can reduce the existing vulnerabilities and build resilience.

There is an increased need for conducting a high rigor research in climate change and agriculture. Currently, most of the work is being carried out by foreign institutions, which are based on large scale extrapolation of the results obtained on a global scale. The results thus obtained can be misleading since they do not consider the regional climatic features of that place. To make an accurate assessment, it is necessary to build a model which is based on a local situation and draws from the global parameters of climate. This is important since the change in inter- and intraannual variability helps to improve the adaptive response. Understanding the intensity of impacts at local scale will help to formulate better adaptation strategies for the specific location/place.

One of the main aspects of climate change adaptation is to make use of the local technologies and innovations, which have been used in the rural areas traditionally to combat the worse situation. These technologies/practices are often low costs and do no harm to the soil. It is important that these practices and technologies get documented and a detailed scientific research is conducted to improvise the gaps if any. There is a high potential that some of them could be scaled up to benefit the communities.

2.14.5.3 Provision of Extension Services

To meet the changing information and technological needs of framers, there is a need for development of new organizations in extension delivery. Such organizations will particularly focus on providing extension services in agriculture to rural poor who are most vulnerable to the negative impacts of climate change. The extension services will cater to the changing information and technological needs in agriculture, developing institutional, market linkages, and increased scientific knowledge.

2.14.5.3.1 Creation of Rural Information Centers

It has been seen that a focus on purely increasing food production is not enough to cater to the needs of the growing population. Several districts in India with high agricultural productivity levels also show high levels of poverty (Haque 2000). It is important to focus on the vulnerable communities i.e., the farmers having small landholdings. These farmers have low access to information and technologies. Further, the net quantity of production from small landholdings is so low that the farmers are not able to get a direct access to markets.

Information centers in rural areas that can advise the poor farmers on what has to be grown in case of seasonal changes and extreme events such as cold and heat waves or flood, and when drought like situation arise. These centers can offer advice on land use, cropping systems to adjust to the changes. These centers will also provide information about the existing trends of market prices and link them to various entrepreneurial hubs where the net produce could be sold at an assured price. A network of such centers linking from district to national levels can help in providing continuous technological support and knowledge to the farmers.

2.14.5.3.2 Developing Institutional Linkages

Under the present scenario, the interlinkages between various institutions working in the area of climate change research, policy, funding, etc., are rather weak. These interlinkages between institutions at various levels, including the Rural Information Centers as earlier proposed will help to strengthen knowledge and facilitate resource sharing. A network of agencies at state, national and international levels should be created for sharing scientific data, best practices, and technological innovations in agriculture to respond to climate change. Establishment of region-specific climate centers will further help to deliver solution and support to farmers in that region by providing access to new technologies and crop varieties.

2.14.5.4 Hazard Proofing

2.14.5.4.1 Establishment of Early Warning System

A slight variation in the temperatures and/or precipitation can affect the crop production. Establishing early warning systems will help to receive the information about weather-related changes especially for the extreme weather events.

2.14.5.4.2 Provision of Insurance Services

There is an increased requirement of providing security to the farmers since the chances of the crop failure have increased. Enabling policies that encourage farm insurance can provide protection from adverse effects on farm production due to natural calamities.

2.14.6 Concluding Remarks

Agriculture sector in India is highly climate sensitive. With the increasing impacts of changing temperatures and precipitation levels, adaptation is crucial for food security and sustenance. In order to make the adaptation practices effective, a systems approach is necessary that follows a multi-pronged approach. The scope and emphasis of current agricultural policies and programs in India is myopic. These programs are often implemented as isolated interventions, not factoring benefit sharing and engagement of farmers and other stakeholders. The cross-sectoral impacts are largely neglected. The Indian agricultural sector needs a facelift where the conventional approach of subsidies and grants should be transformed to simulating investment flows and promoting entrepreneurship. Here technology innovation based on local knowledge is very important. Creative ways and innovations at community levels should be recognized, researched, and blended with modern science and communication technologies.

All these measures will help in building national capacities and resilience and help reduce the vulnerability of small and marginal farmers.

2.15.1 Introduction

To the extent that many studies of the last two decades deepen the understanding about the Amazon tropical forest and more is known about the environmental services it offers, they also increased our level of awareness about the growing threats that this system has been subjected to. In addition to the process of uncontrolled expansion of the agriculture frontier, the Amazon, for its large scale, is an ecosystem highly susceptible to climate at regional and global scales. This chapter addresses issues related to environmental drivers of change in the Amazon: deforestation, climate, climate extremes, and fire. The goal is to present aspects of a synergistic action of these effects and the possible responses of Amazonian ecosystems to these drivers of change: (1) short-term responses as the mortality of some species (biodiversity loss), loss of living biomass with consequent influence on storage, and exchanges of carbon with the atmosphere to (2) long-term responses, such as 'savannization' and Amazon dieback. On the other hand, it has been hypothesized that the forest may show some degree of resilience to tolerate those impacts before starting to respond with degradation of the ecosystems. One of the challenges of Amazonian science today is to find out how close those drivers might be from exceeding 'tipping points' of stability of the Amazonian system. We first review the response of tropical forests in Amazonia to isolated drivers of environmental change, and then analyze potential synergistic effects and forest responses from the perspective of the timescale that they might occur. **Figure 1** depicts the framework of analysis for this review, based on synergistic interactions between major drivers and corresponding physical and ecological responses.

2.15.2 Deforestation

It has been widely recognized that deforestation is the most direct and possibly the most deleterious threat to Amazon ecosystem functioning. Until the 1970s, the 6.2 million km^2 of the Amazon forest remained relatively intact. As a result of government plans for development of the region, deforestation rates began to rise. Incentives for the development of the Amazon region have become incentives for deforestation since then; to encourage the planting of extensive pastures and provide tax incentives for active companies in the region, the government would accept as evidence the removal of vegetation cover (Lima 2005). That took place from the early 1970s to the early 1990s.

From 1978 to 1988, when the National Institute for Space Research (INPE) began calculating estimates of annual deforestation rates, the 10-year average deforestation rate was about 21 000 km^2 year^{-1}. Since then, the rate has oscillated because of the variation in market prices of the main driving forces of deforestation in the region (e.g., timber, cattle, soybeans) and owing to the environmental constraints (**Figure 2**).

Another human activity driving the Amazon forest degradation comprises selective logging. According to Asner et al. (2005), not necessarily the areas degraded by selective logging coincide with fully deforested areas. Selective logging is, therefore, a distinct form of land use in the Amazon. Between 1999 and 2002, selective logging has affected an area greater than 12 000 km^{-2} year^{-1} (Asner et al. 2006). According to INPE, 15 000 km^{-2} of forested areas has been degraded by selective logging in 2007 and 25 000 km^{-2} in 2008.

The Brazilian Amazon occupies nine different nations, but around 80% of deforestation occurs in Brazilian territory

Environmental drivers of change
Primary drivers
Climate: CO_2, temperature, rainfall
Land use change logging/deforest
Secondary drivers
Droughts
Forest fires
Ecosystem Responses
Short term
Forest degradation
"Secondarization"
Tree mortality
Long term
Savannization/ forest dieback
Forest resilience
Deep root water uptake
CO_2 fertilization
Amazon region heterogeneity
Climate seasonality wet and dry season

Figure 1 Anthropogenic drivers acting on the Amazon forest, ecosystem responses, and some aspects of forest resilience.

(Soares-Filho et al. 2006), mainly in the transition zones between savanna and rainforest – southern and eastern Amazon regions – the so-called 'arc of deforestation.' Also at global level, deforestation of tropical forests occurs in hot spots of deforestation, because 50% of deforestation of tropical forests has occurred in only 6% of the forest as a whole (Hansen et al. 2008).

Although soybeans have been assuming increasing importance in the grain market (Nepstad et al. 2008; Sawyer 2008), about 70% of the deforested area in Amazonia has been converted into pasture (Soares-Filho et al. 2006). Another important driving of deforestation rates in Amazonia is paved (Soares-Filho et al. 2006) and unpaved (Perz et al. 2008) roads. Projections indicate that deforestation if left unchecked could

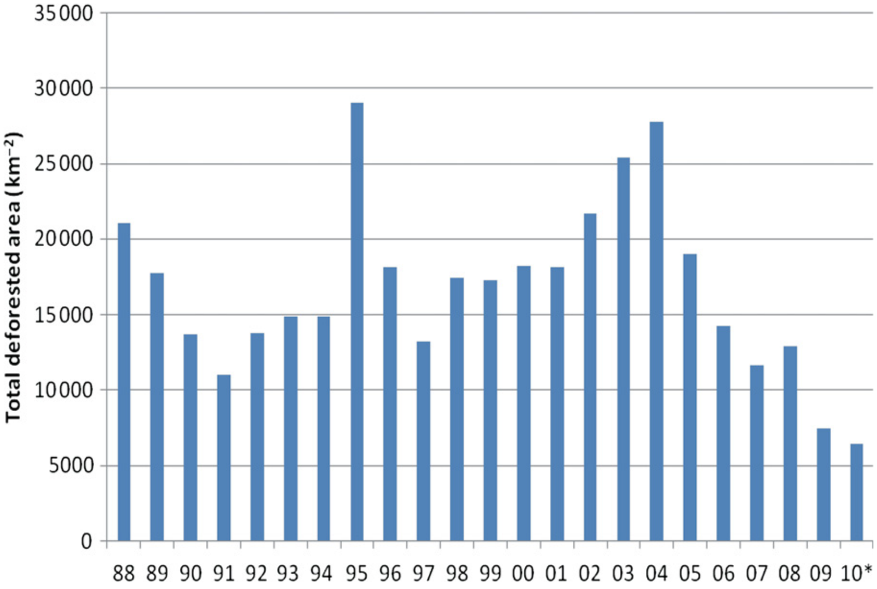

Figure 2 Total annual deforested area according to INPEs (National Institute for Space Research) PRODES program – [Available online at http://www.obt.inpe.br/prodes/index.html].

reach between 30 and 50% of the rainforest area by 2050, even considering the existence of legislation to maintain and protect forest reserves (Soares-Filho et al. 2006).

2.15.2.1 Forest Response to Deforestation and Selective Logging

As a result of deforestation, forest areas are transformed into degraded forest, pasture, and agricultural areas, and may or may not culminate in secondary vegetation areas. This suppression of vegetation can lead to the action of other threats to the Amazon forest, such as increased fire spread and regional climate change. By being a process that begins with the intact forest and ends with the complete conversion of the original forest into other types of land cover, one could imagine that deforestation is a process that occurs suddenly. However, deforestation does not imply an immediate change of the forest landscape in an area of bare soil. Deforested areas are usually replaced by a succession of stages of forest degradation (light, medium, and heavy) to finally into completely degraded areas. The clearcut is the ultimate stage of deforestation, in which the complete removal of vegetation occurs. Throughout the process of forest degradation, pastures represent an alternative use of the area, which can turn or not into agricultural areas. When the area no longer meets the economic interests of trade in timber, livestock, and crops, it is abandoned and changes, according to the environmental conditions, to secondary forest. Deforestation is, therefore, a dynamic and complex process that can take years (http://www.obt.inpe.br/deter/avaliacao/RelatorioMonitoramento.pdf).

The detection of various stages of deforestation through satellite imagery is not an easy task, because the early stages of forest degradation (cutting of the marketable tree species for timber – selective logging) are hard to monitor by using satellite observations. According to INPE data, it is difficult to identify the deforested area before about 50% of it has already been affected (http://www.obt.inpe.br/prodes/metodologia.pdf). In order to monitor the processes of intense clear cutting and the land degradation process of selective logging, INPE has established the PRODES (http://www.obt.inpe.br/prodes/index.html) and DETER (http://www.obt.inpe.br/deter) land cover change monitoring programs.

Another important and potentially deleterious threat to the Amazon ecosystem caused by increased rates of deforestation and selective logging is the increase of fire occurrence. In fact, the clearing of forests and forest impoverishment through logging promote the increased occurrence of fire through the supply of flammable material (dry litter and soil) and the increase in edge areas (interface between forested and nonforested areas), which are more vulnerable to dryness and spread of fire (Laurance et al. 1998; Cochrane and Schulze 1999; Nepstad et al. 1999; Alencar et al. 2004; Barlow and Peres 2004). In addition, degraded forest increases the exposure of the lower layers of the canopy and litter to radiation and increased temperature, increasing their flammability (Aragão et al. 2007).

Under natural conditions of high precipitation index and high atmospheric moisture, the spontaneous occurrence of fire in the Amazon forest is relatively rare. Thus, most species of the forest are not adapted to fire, which hinders their recovery after successive fires. Barlow and Peres (2008) show, after 9 years of field experiment, that changes in forest structure and composition occur in cascade after each event of fire occurrence, culminating in vegetation very similar to an impoverished secondary forest. In this type of vegetation, pioneer species of short life cycle prevail, leading to a significant impoverishment of the environmental services provided by the forest.

Beyond the direct influence on the Amazon ecosystem, deforestation can affect the vegetation through changes in the regional climate. Modeling studies suggest a decrease in the evapotranspiration rates and an increase in atmospheric temperature caused by the large-scale replacement of forest by pasture (Nobre et al. 1991; Sampaio et al. 2007; Costa et al. 2007). It is estimated that these changes will lead to changes in local rainfall patterns, but how big exactly these changes will be is still uncertain. Small-scale deforestation can lead to an increase in local precipitation by the so-called 'wind-effect' (Roy and Avissar 2002; da Silva et al. 2008). On the other hand, large-scale deforestation may act to decrease the precipitation rate. Wang et al. (2009) observed increases in nonprecipitating clouds and decreases in the dry season precipitation over deforested areas in Amazonia. Modeling studies simulating the rainforest replacement by pasture also showed a decrease in rainfall with an increase in deforested areas (Nobre et al. 1991; Sampaio et al. 2007; Costa et al. 2007), with greater effects occurring for deforested area above 40% (Sampaio et al. 2007). In case of decreased rainfall and increased temperature, these local changes can exacerbate the potentially deleterious effects of climate on the Amazon region, described in the following sections.

2.15.3 Climate

Climate change resulting from increased emissions of GHGs, and from other human climate forcing, has the potential to increase the air temperature and related changes in precipitation patterns. Given the sensitivity of tropical forests to these variables, alterations in weather patterns, if pronounced, may result in significant changes in ecosystems and their ecosystems services. On the other hand, changes toward an ecosystem with less biomass can feedback to the climate response, accelerating the process.

Despite the importance of understanding how climate affects the structure and functioning of the tropical forest as we know it today, it has not been an easy task to identify current and plausible future changes in atmospheric variables in these regions. For the Amazonian forest, this is due in part to the scarcity of historical data and, in part, to the natural variability of precipitation (Marengo 2009).

Victoria et al. (1998) identified, based on data from 17 meteorological stations with long records for the period 1913–95, an increase in the air temperature of 0.56 °C century^{-1} with more pronounced variations in late 1960s and early 1970s. This value is similar to the value of 0.57 °C century^{-1}, found by Jones (1994) for South America, and was hypothesized as being mostly caused by increases in anthropogenic emissions of greenhouse gases for the early part of the record. Malhi and Wright (2004), based on data from CRU (CRU Global Climate Dataset, New et al. 1999), identified a much more pronounced increase in the rate of increase in temperature of tropical forests in general, the order of 0.25 °C decade^{-1}. This increase is more pronounced from the 1970s and was attributed by the authors to the global temperature increase caused by greenhouse gases emissions.

It is still more difficult to detect changes in the Amazon precipitation levels for the past and present century. Malhi and Wright (2004) did not record any significant trend of change for the Amazon. Marengo (2004, 2009) studied the 1929–98 period and suggested that there was no significant trend for the entire Amazon, but a slightly negative trend in the north and slightly positive in the south. Li et al. (2008), on the other hand, identified a negative trend in southern Amazon, for the period 1970–99. However, this trend so far has been related to decadal and multidecadal oscillations – natural features of the climate in the Amazon – rather than to an average increase of dry conditions in Amazonia (Marengo 2004, 2009; Marengo et al. 2011a,b; among others).

In terms of predictions, the models used by IPCC are more coherent among themselves in terms of their prediction of temperature increase (between 1.8 and 5.1 °C, under medium scenarios of increased emissions; Christensen et al. 2007) than in terms of changes in the rainfall pattern. Whereas some models project trends in the reduction of rainfall in the Amazon, other models project increases (Li et al. 2006). However, the average of all models simulates reduced rainfall during the dry season in the eastern Amazon and increased rainfall in the wet season in northern Amazonia (Salazar et al. 2007; Saatchi et al. 2007; Lapola et al. 2009; Malhi et al. 2008; Li et al. 2008).

2.15.3.1 Forest Response to the Climate

From the moment that there was an increased awareness that climate conditions like El Niño events could become more frequent or more intense in the future and that the prospects of deforestation associated with climate change could make the Amazon region drier and warmer, modeling experiments and in situ experiments began to simulate the response of forest to these expected conditions.

2.15.3.1.1 Amazon Dieback

One of the first models to include the response of the forest to the changes in climate conditions was the Hadley Center model. According to these model predictions, the annual rates of Amazon rainfall would vary from the current 4.56 to 1.64 mm day^{-1} in 2100, accounting for around 65% reduction (Cox et al. 2000, 2004). Under conditions of increased temperature and decreased precipitation, the Amazon region would suffer, by 2050, a major collapse (the so-called Amazon forest dieback), passing of the condition of slightly carbon sink of around 0.6 PgC year^{-1} (Malhi et al. 2006) to a strong carbon source to the atmosphere – the Amazon forest stores today as much as 90–120 PgC (Malhi et al. 2006; Saatchi et al. 2007) – thus exerting a positive feedback on climate.

2.15.3.1.2 Rainfall Exclusion Experiments

The expected decrease in rainfall in the Amazon forest has also led to field experiments of rainfall exclusion. These are complex field experiments of suppression of throughfall performed in the Tapajós National Forest, east-central Amazonia (Nepstad et al. 2002, 2007; Brando et al. 2008; Markewitz et al. 2010), and Caxiuanã National Forest, the eastern Amazon region (Fisher et al. 2007; Meir et al. 2008), both in Pará State.

The Tapajós experiment showed that the forest starts to increase mortality rates only after about 2.5 years of the induced drought. Concurrently, the rate of litter production only began to show an increase from the third year of dry season throughfall exclusion, in response to water deficit. Lianas, taller trees (overstory canopy) and larger trees (>30 cm diameter at breast height (dbh)), were the more sensitive species to the long-term drought (Nepstad et al. 2007). Wood production is the most sensitive component of living biomass to drought, declining 13% in the first year of exclusion to more than 62% in the subsequent period (Brando et al. 2008). The water uptake by deep roots is the most effective mechanism by which the forest supports, for some period, the decrease in precipitation. At the Tapajós rainfall exclusion experiment, the water uptake by the deeper roots was maintained for a period of about 2 years, showing a sharp decline thereafter Markewitz et al. (2010).

In Caxiuanã, the throughfall suppression was done throughout the year, not only during the dry season (Fisher et al. 2007) as it was in the Tapajós experiment. Unlike the results obtained by Nepstad et al. (2007), the Caxiuanã experiment showed a sharp decline in transpiration during the dry season, caused by the limitation of water transport in the soil-roots in the first year of exclusion. The results suggested that the forest is not able to support a 50% reduction in rainfall over the period of 1–2 years without an impact on the canopy and carbon exchanges. According to Fisher et al. (2007), one of the main differences between the experiments that could have led to different results in terms of forest response to drought was the fact that, in Tapajós, the soil layer was clayey and approximately homogeneous to about 90 m depth. Caxiuanã had a lateritic soil layer of about 4.5 m, which acts as a possible impending layer to the development of deep roots. The vertical extension of the root system and ability to retain water in the soil may therefore have increased the resilience of the forest drought experiment in Tapajós.

2.15.3.1.3 Fire Occurrence

As stated earlier, high levels of atmospheric moisture and dense canopies made the Amazon forest historically resistant to fire. Presently, fire occurrence is located close to road networks and deforestation areas, and, therefore, strongly associated with land use (Cardoso et al. 2003; Cochrane and Barber 2009). Alterations in temperature and precipitation, if severe enough, would change this pattern, possibly changing the fire regime to a condition of greater frequency and severity. At the climate scale, changes toward higher flammability and presence of sources of ignition will favor the species composition that are adapted to and associated with fire occurrence, such as savannas and grasslands (Bond et al. 2005; Cardoso et al. 2008).

2.15.4 Climate Extreme Events and Forest Response

It has been widely recognized that one of the main effects of plausible future climate conditions is an increased frequency of extreme weather events (Bates et al. 2008). This is because of the fact that a warmer atmosphere is able to promote both increased evaporation/evapotranspiration and increased moisture retention in the atmosphere. A crucial feature of temperature increase and climate change is that the water cycle is directly related to climate. At the local level, an increase in atmospheric temperature also increases water evaporation on earth's surface and plant transpiration, thus increasing the atmospheric humidity, which, in turn, is responsible for rain formation. At global and regional levels, different rates of surface warming around the globe move large, cool or warm, dry or moist air masses, which interact with the local atmosphere, thus determining regional climate and, possibly, the severe weather events.

Changes in atmospheric circulation patterns may increase the likelihood of torrential rainfall in some regions and the likelihood of extreme droughts in the other ones (Bates et al. 2008). In general, when most rainfall occurs in the form of short-term torrential rains, surface fast runoff is favored, and less water is stored in the soil profile. This can exacerbate the impacts of dry weather, because during the dry season the river flow is mainly feed by the groundwater, which is replenished by the wet season rainfall (Negrón-Juarez et al. 2007).

Despite the importance of understanding and accurately predicting extreme weather events, global climate models are not yet able to predict them with reliability when run in a hindcast mode. This may be because extreme events of drought have been hypothesized as being related to an increase in surface temperature of the oceans. Thus, future efforts to forecast drought will require the ability of global models to predict changes in surface temperature of tropical oceans (Dai 2010).

For the Amazon region, the extreme events of drought and flood are strongly related to changes in surface temperature of the tropical Pacific (ENSO – El Niño-Southern Oscillation) and the tropical Atlantic (AMO – Atlantic Multidecadal Oscillation). It has been recognized in the literature that changes in surface temperatures of the tropical Pacific Ocean (ENSO) have more influence on the wet season rainfall, while changes in surface temperatures of the tropical Atlantic Ocean have more influence on the duration and intensity of dry season rainfall in the Amazon (e.g., Li et al. 2006; Harris et al. 2008). When the warm waters of the tropical Pacific Ocean (El Niño) precede the anomalous warming of sea surface temperatures (SSTs) of the Atlantic Ocean, it may configure the worst possible climatological/hydrological condition, with interference in the regime of the Amazon river discharge and a range of impacts in the region, as pointed out in various parts of this chapter. The combination of these two climatic features causes a significant reduction of flow in the dry season, as recorded in the drought of 2010 (Marengo et al. 2011a,b).

The connection between the increase in the concentration of greenhouse gases and the increased frequency of El Niño events is still unclear (Yeh et al. 2009). On the other hand, major advances have been made in understanding the connection between the increase in the emission of greenhouse gases and the increase in surface temperatures of the Pacific Ocean (Wang and Dong 2010). According to Cox et al. (2008), the representation of the variation of SSTs in climatic global models caused by the increase of greenhouse gases coupled with the reduced pollution by aerosols in North America give evidence that droughts like the 2005 drought have, currently, a probability of occurrence of 1 in 20 years. However, this probability is hypothesized to increase to one in every two years by mid-century.

Although there are still difficulties to predict the occurrence of severe droughts in the Amazon, extreme events such as those that occurred in the past decades are increasingly better studied and explained in relation to their possible causes and consequences. For instance, the droughts of 1982/83, 1986/87, and 1997/98 (Marengo 1992; Uvo et al. 1998; Ronchail et al. 2002; Marengo 2004) were related to El Niño events of different intensities. Droughts of 1963, 2005, and 2010 were related to the anomalous warming of surface temperatures of the Atlantic Ocean (Marengo et al. 2008a,b; Marengo et al. 2011a,b), but Zeng et al. (2008) have raised the possibility of occurrence of 2002–03 El Niño associated to 2005 drought and Marengo et al. (2011a,b) have identified the occurrence of El Niño-associated 2010 drought.

In case of increased frequency of climate extreme events, it is necessary to take into account the possibility of an increased occurrence of floods in the Amazon. In 2009, the Amazon Basin experienced a flood of magnitude and duration seldom seen in decades. According to Marengo et al. (2011a,b), the rainy season in northern and northwestern regions began in early 2008–09 and was followed by a longer rainy season than normal. This caused the Negro River, the largest tributary of the Amazon, to reach a 107-year record.

2.15.4.1 Forest Response to the Severe Droughts

Before the 2005 Amazon drought, decreasing rainfall in the Amazonia basin had been mainly related to El Niño events, such as the 1982/83, 1986/87, and 1997/98 droughts (Marengo 1992; Uvo et al. 1998; Ronchail et al. 2002; Marengo 2004). The 2005 drought, because of its high intensity, not being associated to an El Niño event, and reaching different areas of basin than the areas normally affected by the El Niño events, was rather a typical and set out new directions of scientific research on climate in the Amazonia region. The drought of 2010 was even more intense than the 2005 drought. According to Lewis et al. (2011), whereas the 2005 drought affected about 1.9 million km^2 of forest, the drought of 2010 affected some 3.0 million km^2.

Unlike what usually occurs with severe drought events resulting from El Niño, the 2005 and 2010 droughts were particularly severe in the Amazon during the dry season, mainly impacting the southern and southwestern Amazonia rather than the northern and eastern regions, commonly affected during El Niño events (Marengo et al. 2008a,b; Zeng et al. 2008; Tomasella et al. 2010; Marengo et al. 2011a,b).

With regards to impacts, there are several studies evaluating the response of forests to drought. At the beginning of the observational research in understanding the Amazon forest as a whole, under the LBA (Large Scale Biosphere-Atmosphere Program – www.lba.inpa.gov.br) several studies have pointed to the fact that evapotranspiration showed an increase in the dry season compared with the values observed in the wet season. The explanation for this behavior was the fact that in the absence of water stress, the dry season had higher evaporative demand (higher solar radiation, higher temperature, less cloud cover, etc.) with consequent increases in photosynthesis. Among the relevant research on this subject we mention the pioneering work of Shuttleworth (1988), followed by the work of Sommer et al. (2002), da Rocha et al. (2004, 2009), von Randow et al. (2004), Souza-Filho et al. (2005), among others. Negrón-Juarez et al. (2007), based on results from experimental sites, report data on precipitation in the range of 3.8–4.3 mm day^{-1} in the dry season and values in the range of 2.5–4.1 mm day^{-1} in the wet season.

The notion that the Amazon rainforest could be resilient to short-term drought probably led to the conclusion, based on remote sensing data, that during the 2005 drought the Amazon forest would have displayed a 'greenness' (Saleska et al. 2007). However, later studies based on field data showed that an extreme event such as 2005 drought has led to the mortality of some Amazon forest species – mainly those of rapid growth and lower density of biomass. This increase in mortality rate meant that in normal years, the forest tends to present itself as a sink for carbon, but in years of extreme drought such as 2005, the forest can act as carbon source for the atmosphere (Phillips et al. 2009).

In addition to increased mortality of the forest, the extreme events of drought can greatly increase the incidence of forest fire, as pointed out by studies conducted by Nepstad et al. (2004), Aragão et al. (2007), and Cardoso et al. (2007), among others.

Although there is a growing recognition that the Amazon rainforest may be adversely impacted by extreme droughts, major issues still need to be better understood. Among them, we mention: Would the impacts of drought be relatively homogeneous throughout the length of the Amazon rainforest? What is the influence that factors such as chemical and physical composition of the soil, water table depth, moisture retention characteristics, and type and composition of vegetation could exert on the response of forest to extreme drought? Are the drought effects irreversible? How strong is the phenomenon of hysteresis? These issues, along with aspects related to the forest resilience to droughts, have been the subject of intensive research by the scientific community.

2.15.5 Factors of Forest Resilience

The drivers of anthropogenic changes in the Amazon region give us the notion that the forest has been subject to growing threats, which can lead to a collapse of the ecosystem. However, we cannot fail to consider, in this scenario, that there are factors that can provide a certain degree of forest resilience, that is, the ability of the forest to maintain its integrity when subjected to disturbance (Holling 1973).

A key factor, historically noted as able to provide some forest resistance to drought, is the assimilation of water from deeper layers of soil through deep root systems (Nepstad et al. 1994; Hodnett et al. 1996). This ability has been recognized through field experiments over time and is reinforced by observations that there are regions of the Amazon forest that display evergreen leaves, even during the dry season, which normally lasts 3–5 months (Nepstad et al. 1994; Myneni et al. 2007). Additionally, the ability of forests to remove water from deeper layers was identified as being responsible for the initial forest resilience shown during the first years of rainfall exclusion in the Tapajós site. At the same time, a potential barrier to deeper penetration of roots may have reduced the resilience of the forest in the Caxiuanã experiment (Nepstad et al. 2007; Fisher et al. 2007; Markewitz et al. 2010).

An additional mechanism that is pointed out as able to provide forest resilience in the long term is the so-called 'CO_2 fertilization' effect. As a result of the increase of atmospheric carbon, the CO_2 fertilization effect decreases the net loss of biomass caused by increased droughts. Because the plant stomata needs to open less for assimilation of the same amount of CO_2, the plant loses less water through transpiration, increasing the efficiency of water use and being less sensitive to soil moisture loss (Lloyd and Farquhar 2008). However, it is still unclear whether the decrease of transpiration in large scale may have the potential to change the local precipitation.

Another problem arising from the CO_2 fertilization is, according to Phillips et al. (2009), the possibility that pioneer species such as lianas gain advantage of the increased CO_2 in the atmosphere. Whereas these fast-growing species have lower wood density, its competitive advantage there could cause a decrease in the amount of carbon stored in the forest.

The great extent and heterogeneity of the Amazon forest is another important point that needs to be taken into account when considering the threats to the rainforest. It cannot be expected for a region with spatial dimensions of the same order of magnitude as the European continent to homogeneously respond to the rainfall reductions, increasing droughts, and fires. According to Killeen and Solórzano (2008), for example, the northwestern region normally shows high rainfall rates resulting from the winds going upslope in the Andes mountain ranges (Nilo and Nobre 1991), and thus would be less susceptible to critical levels of precipitation.

Another important aspect that might confer some degree of forest resilience to extreme events of drought is the existence of a well-pronounced seasonality between periods of drought and flood in lowlands and between dry and wet seasons in the areas of land in the region. The elevation of groundwater level during the wet season feeds the water table, which, associated with the soil water retention properties, is responsible for the maintenance of soil moisture that feeds the deep roots during the dry season. According to Negron-Juarez et al. (2009), it is the rain of the wet season that provides much of the groundwater accessed through the forest during the dry season. In the same sense, flood events, despite the deleterious impact they may cause on the riverine community and eventually on the forest response (anoxic conditions associated with high levels of water can promote tree mortality) have the potential to recharge the underground water reserves.

2.15.6 Changes in the Equilibrium State – Savannization

According to Scheffer and Carpenter (2003), abrupt changes could occur in some ecosystems and the theory suggests that the occurrence of these changes is due to the fact that there is more than one stable equilibrium state for this ecosystem.

This implies that gradual changes in temperature or other environmental factors may have little effect on the ecosystem until a threshold is reached. From this threshold, abrupt changes difficult to reverse occur. The possibility of more than one steady state to the Amazon region has been identified by scientific research for over three decades. From the moment in which scenarios of large-scale deforestation began to point to the possibility of an Amazonian rainforest climate more similar to a savanna region, possible changes in vegetation began to be investigated (Nobre et al. 1991). Then, with the prospect of a plausible future drying of the Amazon, these studies have intensified (Oyama and Nobre 2003; Scholze et al. 2006; Salazar et al. 2007; Vizy and Cook 2007; Lapola et al. 2009).

Oyama and Nobre (2003) found the existence of multiple stable equilibrium states in tropical South America in the current climate conditions and a set of plausible future climate conditions for a global atmospheric circulation model (CPTEC/COLA AGCM) coupled to a vegetation model potential (CPTEC-PVM). Two stable equilibrium states were found. One corresponds to the current distribution of Amazon forest and savanna biomes. The second corresponds to a new equilibrium state, in which forests are replaced by savannas mainly in the eastern region. Scholze et al. (2006) quantified the risk of forest loss as a result of climate effects. Thus, a dynamic vegetation model (LPJ-DGVM) was forced with 52 scenarios and 16 climate models, mapping the natural variability of fire frequency and supply of freshwater. The authors grouped the responses of ecosystems to warming simulated amounts of less than 2 °C, 2–3 °C, and more than 3 °C. The Amazon region is included among the regions that show increased risk of forest loss, with related increased savanna area and frequency of fire.

Salazar et al. (2007) studied the consequences of plausible climate scenarios on the distribution of biomes in South America in the twenty-first century by forcing a potential vegetation model with climate scenarios from 15 IPCC models, considering two IPCC emission scenarios (A2 and B1). In both scenarios, the results indicate a reduction in tropical forests and an increase in the region covered by savannas. The decrease in the area of rainforest in South America is 18% for the period 2090–99 for the A2 scenario (worst case). The regions of the tropical forest reduction are mainly concentrated in the southeastern Amazon. These changes were attributed by the authors to a decrease in soil moisture and/or an increase in the dry season. Cook and Vizy (2006) forced a model of potential vegetation (CPTEC/PVM) with results of a regional climate model grid of 60 km (MM5-MRS) to study the implications of climate projected for the twenty-first century (IPCC AR4 CCCMA) on vegetation of tropical and subtropical South America. The scenario of future climate is simulated using the increase of levels of atmospheric CO_2 to 757 ppmv. The coupled regional climate model predicts a 70% reduction in the extent of rainforest in the late twenty-first century and an expansion of savanna in the northeast. Lapola et al. (2009) investigated the distribution of rainforest and savanna biomes of South America using climate projections and a series of estimates of the increase in atmospheric CO_2 concentration. These authors concluded that, if the CO_2 fertilization effect in fact occurs and is maintained for a long time, it would be able to avoid changes of biome in most climate scenarios, even if the CO_2 fertilization effect is halved. However, regardless of whether fertilization effect is considered or not, if in the future the dry season is longer than 4 months, then a replacement of tropical forest by a less productive biome such as forms of tropical savanna is expected.

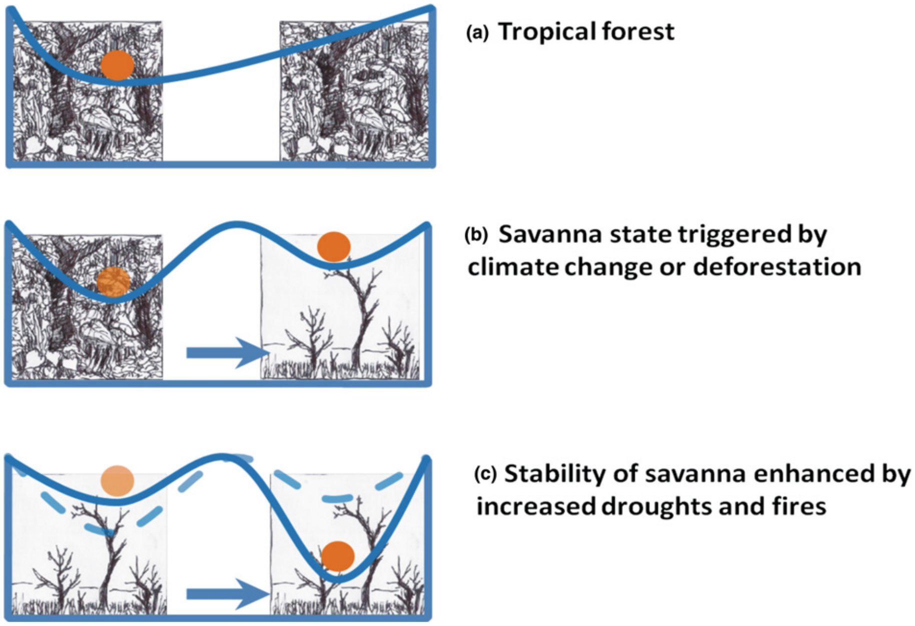
The sequence of change of stability of the Amazon forest and savanna biomes is illustrated in Figure 3. Figure 3a shows the steady state of the tropical rainforest, as it is today. Figure 3b shows the possibility of a second state of equilibrium – the occurrence of savanna forced by large-scale deforestation and climate. Figure 3c shows that the increased occurrence of fire associated with a greater frequency of extreme events of drought can enhance the stability of the condition of savanna, making it even more difficult for the condition of the Amazon forest to recover.

2.15.7 Synergistic Effect of Deforestation, Drought, and Fire – Are We Close to a Tipping Point?

The impacts of deforestation in the Amazon will most likely be exacerbated by the synergistic interactions between the local and regional climate including increased frequency of drought and fire occurrence. Studies have shown that large-scale deforestation can lead to an increase in temperature and decrease in evapotranspiration, with potential reduction in precipitation. Associated with deforestation, climate effects caused by GHG emissions emerge as an indirect threat to the Amazon ecosystem, acting, according to some models results, to further reduce the precipitation with concomitant increases in temperature. Most of the simulations projected decreases in rainfall during the dry season, especially in the eastern Amazon (Malhi et al. 2008). However, recent drought events that occurred in the Amazon in 2005 and 2010, associated with the warming of the tropical Atlantic Ocean, showed that western, southwestern, and southern Amazon are also subject to extreme seasonal drought (Marengo et al. 2008a,b; Tomasella et al. 2010; Lewis et al. 2011).

Under natural conditions (high rainfall, high atmospheric humidity, and high soil moisture) the Amazon forest is not sensitive to the occurrence of fire. However, this condition of low vulnerability to fire has been shown to be unstable in the face of numerous changes imposed by direct or indirect human actions: for example, loss of biomass associated with increased mortality in some species owing to the events of drought, increased edge effects, and forest degradation by logging; increased temperature; and decreased atmospheric humidity and soil moisture associated with soil management practices based on the use of fire. Increasing the incident radiation that penetrates through the canopy, increasing the temperature, drying litter, and providing more fuel for burning greatly increase the flammability of the forest.

Aragão et al. (2008) analyzed the interactions between rainfall, deforestation, and fires during the period 1998–05 in the Brazilian Amazon. The results showed that both deforestation and hot spots reach a maximum value during the dry season (June–September). The highest peak of deforestation was observed in May, whereas peaks of fire occurrence coincided with the months of less rainfall (August and September, in other words approximately 3 months after the rainy season reaches its peak deforestation). This is the time required for,



(a) Tropical forest
(b) Savanna state triggered by climate change or deforestation
(c) Stability of savanna enhanced by increased droughts and fires

Figure 3 Influence of the driving forces of deforestation, climate change, extreme events of drought, and fire on the bi-stability of the Amazon ecosystem.

later in the dry season, the wood to dry and be ready to be burned. At that time, the outbreak of fire reaches its maximum. Additionally, Aragão et al. observed that the cumulative number of outbreaks of fire was linearly related to the size of the area deforested annually for the period 1998–04. During the year 2005 because of drought, the number of hot spots increased by 43% compared to that expected for a similar area of deforestation ($\sim$19 000 km^2) in a normal year of drought.

A number of authors have raised the possibility of a tipping point for the Amazon (Scholze et al. 2006; Sampaio et al. 2007; Nepstad et al. 2008; Malhi et al. 2008; Nobre and Borma 2009). The review by Nobre and Borma (2009) presents a table with the main qualitative and quantitative results obtained so far, to identify potential tipping points for the Amazon ecosystem. The values that emerge from the use of different types of models that simulate the earth system are $T > 3\,^\circ C$ (Scholze et al. 2006; Salazar et al. 2007; Salazar and Nobre 2010) and deforestation area greater than 40% (Sampaio et al. 2007). However, these projections do not consider the occurrence of fire, which can greatly advance the prospect of collapse simulations based solely on changes in climatic conditions.

2.15.8 Conclusions

The analysis carried out in previous session leads to the conclusion that there may be limits to environmental drivers of change in the Amazon that should not be exceeded if one wants to maximize the likelihood of long-term survival of regional ecosystems and the local, regional, and global ecosystems services they provide to humankind. Therefore, it is important to examine the implications of the suggested thresholds in terms of climate and regional deforestation for Amazonian countries and international policies.

Let us start by the first limit on global warming, that is, $\Delta T_{\text{global warming}} < 3\,^\circ C$ (3.5 °C in the Amazon). Limiting global warming to less than 2 °C by early and sharp reductions of global emissions would put the system on safe ground because this is sufficiently far from the tipping point of 3.5 or 4 °C, although it does not guarantee that there will be no impact, especially on biodiversity. However, that reduction depends very little on Amazonian countries' policies, because global emissions arising from tropical land use change are only about 10% of global emissions (Global Carbon Project 2010).

The other threshold comes from land use change, that is, Total Deforested Area must remain less than 40% of the total basin area to increase the chances for forest permanence. This constraint clearly depends directly on Amazonian countries' policies for land use change and development. Policies to rapidly reduce deforestation (e.g., maintaining 80% of forests in rural landholdings as is with the current land use policy in Brazil) apparently have had a positive impact in the last 6 years.

In close association with land-use and -cover change, increases in fire occurrence represent other important driver of change in forests of Amazonia. Fires close to the edge of forests can extend the direct damage from deforestation further into pristine areas and enhance the likelihood of future burnings. In addition, because species in the tropical forests are not adapted to fire, additional burnings can lead to important changes in species distribution and composition.

Taken all together, deforestation, fires, and changes in climate and the frequency of its extreme events represent a set of drivers with strong potential for environmental changes in Amazonia. Considering them is essential in government actions for future land-use policy in the region. Even their isolated effects will likely have a high impact in the future of the region. Accounting for the synergy of their effects adds the perspective for changes that can be even faster.

The extent to which the combined effects of the major drivers of environmental change we discussed will lead to fast and perhaps irreversible changes in the ecosystems of Amazonia is an important subject of research. Although it makes sense that their synergistic effects are potentially catastrophic, factors of forest resilience such as resistance to drought or CO_2 fertilization can slow down these effects or prevent them. Concern on surpassing the forest's resilience levels, however, is still an important issue.

In order to maximize the likelihood of long-term survival of the ecosystems in Amazonia and the local, regional, and global ecosystems services they provide, important scientific questions should be addressed in the future, so new perspectives for land-use policy in the region can be considered. For example: What are the thresholds for irreversible changes in the region and how close are we from reaching these values? Are we considering all the major precursors of change related to anthropogenic activity in the region? In our view, considering all these questions only reinforces the need for environmental protection of the region.

2.16.1 Introduction

Climate and humanity interact and feedback on a variety of scales. At a very local level, human actions release greenhouse gasses and aerosols. On a broader scale, the atmosphere mixes and integrates these pollutants, producing a spatially uniform, and rapidly increasing radiative forcing. Far from where this sequence began, the radiative forcing further warms the already very warm waters of the tropical Indian and western Pacific oceans. This warming, in turn, produces strong overturning climate anomalies that appear to be modifying the climate of eastern and southern Africa (**Figure 1**). At a very local level again, in eastern and southern Africa, some of the world's most vulnerable, poor, and food insecure populations experience changing climate means and variances, and begin to adapt their livelihoods to that new reality, sometimes in ways that ultimately strengthen this feedback loop of climate and adaptation. This interdisciplinary study focuses on the feedback between climate and adaptation, as represented by the interaction of climate, land cover/land use, and population growth in Ethiopia, one of the world's most food insecure countries.

To understand and inform agricultural adaptation to climate and variability in Ethiopia requires investigation across all of the multiple scales described above. Both 'bottom up' and 'top down' climate analysis approaches (**Figure 1**) must be combined with a temporally dynamic and area-specific understanding of Ethiopian population, land use, and livelihoods. Since 2005, our climate analyses have combined detailed evaluations of local rainfall trends with diagnostic analyses of large-scale climate evaluations. This work was prompted by the identification of a pattern of rainfall declines across densely populated, agriculturally important, and vulnerable areas of south-central and southern Ethiopia (Funk et al. 2002). A series of increasingly detailed diagnostic analyses have suggested, with increasing clarity and evidence, that these drying trends are tied to large, and at least partially anthropogenic, warming in the Indian Ocean and western Pacific (Funk et al. 2005; Verdin et al. 2005; Funk et al. 2008; Funk and Brown 2009; Williams and Funk 2011; Williams et al. 2011). The warm waters of the tropical Indian and western Pacific warm pool are very near to the thermal maxima that can be created by the interaction of radiative warming and local evaporation (Newell 1979), and closely track with global temperatures and anthropogenic radiative forcing. This warming has increased the rate of convection, rainfall, and diabatic heating in the Indo-Pacific warm pool, and helped trigger more frequent droughts across southern and south-central Ethiopia.

It is not only the magnitude but the location of these rainfall declines that has made them so important. Ethiopia's population is heavily concentrated in the south-central portion of the country. These food insecure populations typically practice rainfall-dependent agricultural, agro-pastoral, or pastoral livelihoods. Topography strongly modulates both the mean climate and the spatial livelihood patterns (**Figure 2**). Farm families typically occupy the cool highland regions receiving copious rains, while pastoralists live on the hot dry lowlands, and agro-pastoralists live in-between the two (Livelihoods Integration Unit 2010). Higher elevations receive more rainfall than low arid areas while supporting agricultural livelihoods and higher population densities. The population density of these areas dramatically varies (Livelihoods Integration Unit 2010), from over 300 people per km^2 in some parts of south central Ethiopia to less than 10 people per km^2 in areas dominated by pastoral livelihoods. Most rural people live in

the highlands and middle-highlands, which comprise only one-third of the country, and this population tends to be primarily concentrated in the south-central portions of the country. The seasonality of rainfall varies in these areas. In the eastern Somali region, rains come twice a year – during the March–June *Belg* season and during the October–December *Deyr* season. In the south-central portion of the country, most areas receive both *Belg* and summer (June–September) *Kiremt* rains. Many farmers plant slowly maturing but high yielding 'long cycle' crops that mature across both the *Belg* and *Kiremt* seasons.

Population pressure plays an important role in Ethiopian food insecurity. In 2011, Ethiopia contained 90.9 million people (CIA 2011) and had a population growth rate of 3.2% (a doubling time of 22 years). Preplanned assistance provided by the Productive Safety Net Program supported some 7.4 million people, while an additional 4.5 million people required emergency humanitarian assistance due to poor rains and extremely high food prices (FEWS NET 2011). These 4.5 million people tended to be located in the south-central, southeastern, or eastern part of the country. Approximately 65% of these at-risk households primarily relied on agricultural livelihoods; the remainder were pastoralists or agro-pastoralists. In 2010, the country received by far the lion's share of World Food Program aid (24%), followed by 13% for Pakistan and 8% for Sudan. In 2011, Ethiopia faced the results of terrible rain deficits in the boreal winter and spring, and the resultant massive food emergency required an even greater expenditure of food aid.

As Ethiopia's population has grown, the land under cultivation has rapidly expanded (Funk et al. 2008). Important issues involve how these land cover transitions interact with local alterations of climate and whether these patterns of agricultural expansion could make Ethiopia more or less food secure in the near future. This study combines an evaluation of local climate trends and land cover change to briefly address these questions.

2.16.2 Methods and Data

This study uses three data sets: the Famine Early Warning System Network Trend Analysis (FTA) (Funk et al. 2011), Collection 5 land cover classifications (Friedl et al. 2010) derived from National Aeronautic and Space Agency's (NASA) Moderate resolution imaging spectrometer (MODIS), and the 2008 Landscan gridded population data set (ORNL 2011). These datasets provide detailed information about climate, land use, and population on a local scale. Our focus here is on making an interdisciplinary, nonquantitative evaluation of their joint spatial distribution and temporal tendencies. We do not address, except in passing, the underlying causes of the observed trends; our focus here is on their potential interaction as an example of effect of multiple vulnerabilities of Ethiopian agriculture. We do assume, however, that the large scale climate or socioeconomic or demographic drivers are such that the trends are likely to persist for the next 10–20 years. We acknowledge the uncertainty of such an assumption, but feel it is warranted because the local climate trends appear linked to slowly varying, at least partially anthropogenic, climate variations in the Indo-Pacific and because the population and land cover changes are tied to patterns of demographic or social inertia.

2.16.2.1 The FTA

To map the local mean and velocity of Ethiopian rainfall patterns, this study uses the FTA. The FTA fields (Funk et al. 2011) use satellite mean fields and environmental predictors (Table 1) to guide the spatial interpolation of station data to create a large number of point estimates of long-term means and decadal trends. The approach involves exploratory analysis and selection of a relatively small number (typically four to six) of predictors and the identification of a characteristic scale primarily determined by station density. Core to the FTA model-fitting are the local spatial correlations between station data and satellite and environmental predictors. At a local scale, satellite fields typically exhibit a strong spatial covariance with in situ observations, and this can be used to make accurate long-term mean and trend maps. Satellite fields also typically exhibit local spatial correlations that are much stronger and more consistent than physiographic fields. The local slopes of mean satellite-based rainfall estimates are better related to the true slope than indirect proxy indicators, such as the terrain elevation or slope.

The methodology was developed using a multivariate set of predictors including physiographic variables (elevation and slope) from the GTOPO30 data set, satellite observations of rainfall (RFE2, Xie and Arkin 1997), infrared brightness temperatures (Janowiak et al. 2001), and MODIS Land Surface Temperatures (Wan and Dozier 1989). The first step used moving window regressions to create a 'first cut' estimate of the gridded field, estimated at each target grid cell (i.e., each 0.1° cell across the maps). Each station value was then paired with the closest grid cell, and the regression model errors (residuals) were estimated. A model of the spatial structure of these errors was then used to produce another grid of values. Because the model of the spatial structure explicitly quantifies the spatial decorrelation with increasing distance, the interpolation produces spatial maps of standard error, contingent on the spatial distribution of the observation network. The moving window regression and residual fields were summed, creating an estimate that combines correlated exogenous predictors and the spatial covariance of the *in situ* observations. At each grid location, the final estimate combines the local regression estimate with the interpolated residuals.

Table 1 Climate data modeling products

Satellite observations	*Time period*	*Source*
MODIS land surface temperatures [°C]	2003–09	NASA
Meteosat infrared brightness temperatures [°C]	2001–09	NOAA/CPC
Merged rainfall estimates versus 2 [mm]	2001–09	NOAA/CPC
Physiographic predictors		
Latitude [°]	N/A	N/A
Longitude [°]	N/A	N/A
Elevation [m]	N/A	USGS GTOPO30

One advantage of the approach taken here, which calculates at-station changes and then interpolates the results, is that it supports the explicit estimation of interpolation errors. This allows us to address the following question: Does the density of the observed station network truly support the mapped trends? This degree of certainty can be represented as 'sigma fields,' calculated by dividing the interpolated trends by the interpolation standard errors; these provide a means of visualizing the statistical significance of the observed climate trends, vis–à–vis the spatial uncertainty field. The results presented here are supported by a dense network of gauge observations, obtained from Ethiopia's national meteorological agency, and the downward trend magnitudes for southern Ethiopia are typically around five times greater than the associated standard errors.

The analysis presented here is based upon the rainfall trend and mean fields for Ethiopia's boreal spring (March–April–May–June, MAMJ) and boreal summer (June–July–August–September, JJAS). The MAMJ and JJAS rainfall trends are based on the difference between the 1960–89 and 1990–2009 means, calculated from the station data. The MAMJ and JJAS rainfall climatologies were based on the 1960–89 period. The rainfall trend background models were based on longitude, latitude, elevation, land surface temperature, and infrared brightness temperature data. The rainfall climatology background models were based on the same fields and mean RFE2 rainfall estimates.

2.16.2.2 Land Cover Change Analysis

In conjunction with rainfall trends, this study also examined changes in land cover, as represented by the NASA MODIS Collection 5 global land cover-type classification maps (Table 2). The 500-m annual MODIS Collection 5 land cover data set uses neural networks and decision trees in conjunction with multitemporal reflectance data, spatial textures, enhanced vegetation index data, snow cover, land surface data, and terrain elevation to produce global land cover classifications using several land cover schemes (Friedl et al. 2010). In this study, we used the International Geosphere Biosphere Program (IGBP) scheme, which includes 11 natural vegetation classes, 3 developed and mosaiced land classes, and 3 nonvegetated land classes (Table 1).

The forested classes of the IGBP categories were merged and smoothed using 5 × 5 moving windows and 3-year composites. One composite period corresponds to the beginning of the study period (2001–03). The second period corresponds to 2006–08. For each 500 m pixel, 75 land cover values (from the surrounding 25 pixels, for each of the 3 years) were examined, and the most frequent cover type was estimated. This approach was used to dampen the impacts of interannual climate variations and to focus on the large-scale patterns in land cover/land use change.

Pixels that transitioned from forest to crop or forest to mixed natural vegetation and crop between 2001–03 and 2006–08 were then identified and related to 14 predictors: elevation, slope, distance to rivers, tree cover %, maximum normalized difference vegetation index (NDVI), NDVI fragmentation, cover-type diversity, distance to cover-types, distance to roads, distance to villages, population density, mean annual temperature, mean annual rainfall, and precipitation of the driest month. A large number of forest-to-crop transitions were identified over south-central Ethiopia. To explore the drivers of these transitions, the transitions were modeled using logistic regression (LR). LR is a special case of multiple regression in which the dependent variable is discrete (Hosmer and Lemeshow 2000), such as land cover types. LR was used to assess which of the 14 independent variables were the most effective predictors of forest-to-crop and forest-to-mixed natural vegetation and cropland transitions.

Table 2 Initial IGBP land cover classes used in modeling cover changes in Ethiopia

2008 LandScan population data (Dobson et al. 2003) provided a third input to our analysis. This 30 arc-second resolution population data set disaggregates subnational census data based on likelihood coefficients that are based on proximity to roads, slope, land cover, and other information. Coarser resolution, multiyear, Gridded Population of the World population estimates (CIESEN 2011) were used to assess population change over time. Crop statistics from the United Nations' Food and Agriculture Organization were also evaluated.

2.16.3 Results

2.16.3.1 Local Variations of Climate

Between the mid-1970s and late 2000s, *Belg* and *Kiremt* rainfall, based on quality-controlled station observations, decreased by 15–20% across parts of southern, southwestern, and southeastern Ethiopia. We have described these declines in two ways: as a contraction of the areas receiving adequate rainfall for viable agricultural livelihoods (assumed to be greater than 500 mm of rainfall per rainy season) and as a map of anticipated changes in rainfall and temperatures (assuming a persistence of patterns observed).

Ethiopia receives most of its rain between March and September. Rains begin in the south and central portions of the country during the *Belg* season, then progress northward, with central and northern Ethiopia receiving the most precipitation during the *Kiremt* season. Rainfall totals of more than 500 mm during these rainy seasons typically provide enough water for viable farming and pastoral pursuits.

While local alterations in climate can be interpreted in many meaningful ways, one simple, and powerful, approach is to look at changes in the ‘front lines’ of climate suitability; transition zones between areas that were, and soon may not be, viable for a given livelihood pattern. In Ethiopia, transitions between viable and nonviable cropping conditions align, approximately, with the 500 mm isohyets in seasonal rainfall totals. **Figure 3** shows these isohyets for the MAMJ and JJAS seasons for the 1960–89 average, the 1990–2009 average, and a 2025 projection. Note that this 2025 ‘projection’ combines 20 years of observed change (1990–2009) with 16 years of predicted changes, based on a persistence of recent trends (a linear extrapolation). This is the approach used for the scenario generation of plausible future local climate. The areas that appear likely to experience a contraction have been shaded to emphasize that they may be areas of emergent risk. These regions will likely experience a substantially higher frequency of droughts, subjecting households to the repetitive shocks that decrease resilience and help feed a spiral of poverty.

Between 1960 and 1989, the area receiving (on average) this much rain or more during the *Belg* season was large, over 215 000 km^2. For the *Belg* season, this area is shown in light brown in the upper left panel of **Figure 3** and should be understood to lie beneath the dark brown and orange areas. Over the past 20 years, the areas receiving sufficient *Belg* rains have contracted by 16% (dark brown polygon), exposing densely populated areas in the Rift Valley, in Southern Nations, Nationalities and People's Region, and Oromia, where agriculturalists face near-chronic food insecurity (see Objectives and Methods section below for location and population totals). A continued decline in rainfall could result in a contraction of the area receiving more than 500 mm during the *Belg* season (orange polygon) by another 16%. In the eastern highlands, future *Belg* rains appear threatened as well.

(b) Average location of the June–September 500 mm rainfall isohyets. (c) Average location of the March–September 900 mm rainfall isohyets. (d) Average location of the March–June 250 mm rainfall isohyets. The semitransparent purple overlay shows the areas with 2007 population densities of greater than 100 people per km^2. The yellow shading in the background delineates agricultural areas; the gray background delineates agro-pastoral and pastoral livelihood areas (cf., **Figure 2(b)**).

These affected areas have approximately 16.6 million inhabitants (based on 2008 Landscan data).

During the *Kiremt* season, between 1960 and 1989, the area receiving (on average) more than 500 mm is shown in light brown in **Figure 3(b)**. Over the past 20 years, the areas receiving sufficient *Kiremt* rains has also contracted (dark brown polygon), exposing many of the same Rift Valley populations in SNNPR and southern and eastern parts of Oromia. These affected areas have approximately 12.6 million inhabitants (based on 2008 Landscan data).

March–September 900-mm rainfall accumulations, which directly relate to the performance of slow maturing 'long cycle' crops (**Figure 3(c)**), exhibit large areas of reductions in rainfall, running in a band that stretches from the eastern highlands to south-central Ethiopia. The 900 mm threshold was chosen because it coincides with the extent of long cycle cropping examined in previous FEWS NET studies. Approximately 20.7 million people live in these affected zones. Poor long cycle crop performance in the south-central and eastern midlands and highlands could directly affect the livelihoods of many of these people, while adding pressure to national cereal prices.

Figure 3(d) especially relates to climatic patterns observed in pastoral zones. It shows the northwestward retreat of the 250 mm *Belg* season March–June isohyets between 1960–89 and 1990–2009, and as projected forward for 2010–39. While the October–December *Deyr* rains have exhibited little trend (not shown), observed rainfall declines during the *Belg* season are reducing the quantity and quality of viable pasturelands. More frequent droughts in these areas are making it difficult for livestock to recover from poor rainy seasons. The area of contraction affects a total population of approximately 7 million. Note that even dryness in the *Belg* and *Kiremt* crop growing areas also impacts pastoralists and agro-pastoralists by contributing to higher cereal prices and leading to lower terms of trade when livestock are traded or sold for food.

2.16.3.2 Declining Rainfall in Densely Populated Areas

The purple areas in all panels of **Figure 3** highlight very high population densities; many of these most densely populated areas are affected by the described March–June, June–September, or March–September rainfall declines. The correspondence between the high population densities in the south-central Rift Valley area and the receding long-cycle (March–September) rainfall pattern is of particular concern. This area is heavily populated, all available fertile land has been cultivated, and the size of land holdings is diminishing as population grows. It appears likely that the combination of population growth, land degradation, and more frequent droughts will result in more frequent food-related crises.

2.16.3.3 Observed Changes in Rainfall and Temperature Projected Forward

Figure 4 projects the spatial patterns and quantities of future rainfall reductions and temperature increases by extending the rate of observed 1960–2009 changes for each season, through the 2010–39 period, based on an assumed persistence of the observed trends. For the *Belg* rains, rainfall declines range from −150 to −50 mm across the south-central and eastern portions of the country and will be associated with lower *Belg* harvests and poorer pastoral rangelands during the summer and early fall. This may be particularly disruptive for pastoralists and agro-pastoralists living in southern Oromia and western Somali regions who, at present, already rely upon meager *Belg* rains for their livelihoods. For the *Kiremt* rains, rainfall declines range from −150 to −50 mm across the western and southern portions of Ethiopia. The combined *Belg* and *Kiremt* rainfall reductions total a loss of more than 150 mm of rainfall per year in the most heavily populated **(Figure 2)** long cycle crop growing area of the country.

If recent warming trends continue, and they are very likely to, most of Ethiopia will experience more than a 1.0 °C increase in air temperature (**Figure 4(b)**, bottom) with the

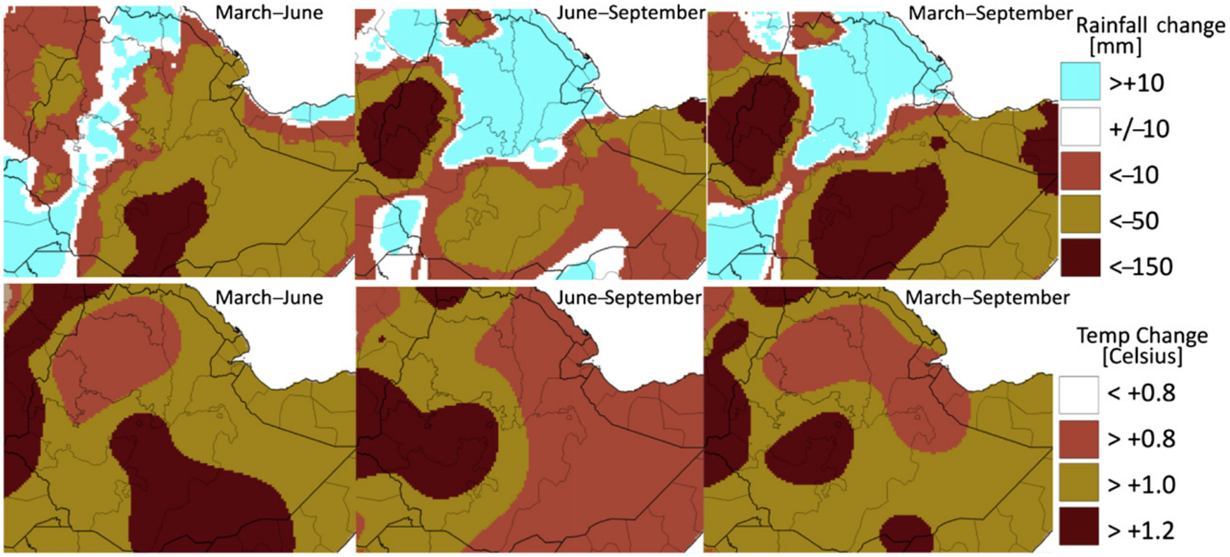

Figure 4 Observed and projected change in March–June, June–September, and March–September rainfall (top) and temperature (bottom).

warming tendency projected to be greatest in the south-central portion of the country. This warming will intensify the impacts of droughts and could particularly reduce the amount of productive cropland for coffee, since coffee plants typically prefer temperatures cooler than 22 °C.

The results in Figures 3 and 4 help us interpret the *local* climatic impacts, presuming, of course, persistence in the observed rates of rainfall decline. Unfortunately, the location of the retreating isohyets in Figure 3 tends to coincide with some of the most densely populated areas in Africa, with Landscan 2008 population densities of over 350 people per km^2. While estimating 'exposure' to climate variability is difficult, it seems likely that millions of people within the retreating contours will face recurrent food crises, as seems to have already been the case over the past decade (www.fews.net).

2.16.3.4 Land Cover Change Analysis

While the trends shown in Figure 4 and the retreating isohyets shown in Figure 3 are worrisome, it is important to recognize that there are vast areas of Ethiopia where the agro-climatic conditions have been stable or even improving. Ethiopia's steep topography and the associated steep climatological rainfall gradients provide a natural resistance to some climate variation. Even in dry years, most of north-central and north-western Ethiopia receives plentiful rainfall. The climatic security of these 'water towers' may be one reason that the country has such a long history of continuous settlement and government. It is also worth noting that the northern parts of the country have not exhibited the same downward trends as the south (Funk et al. 2011; Williams et al. 2011).

It is important to identify, therefore, *where* in Ethiopia agriculture is expanding. Different spatial patterns could have very different implications for future food security. Expansion in the climatically secure north might decrease interannual variation in national cereal production, increasing the country's agricultural resilience to climatic shocks. Expansion in the south might increase the year-to-year variance of crop yields and amplify Ethiopia's exposure to rainfall declines.

Are patterns of agricultural extensification located in the relatively secure central or north-western parts of the country? One answer to this question, as depicted by 2001–03 and 2006–08 MODIS Collection 5 land classifications, is shown in Figure 5. According to the MODIS Collection 5 classifications, most of the forest-to-crop transitions in Ethiopia have predominantly occurred in the south-central portions of the country, where population densities are high (Figure 2). For both the forest-to-crop, forest-to-mixed crop, and natural vegetation classes, the spatial pattern of transitions is heavily slanted toward the southern half of the country. These areas, in general, are associated with drying and warming trends (Figure 4) and retreating *Belg*, *Kiremt*, and long cycle contours (Figure 3).

We formalize these relationships by using logistic regression (Hosmer and Lemeshow 2000) to examine the predictive power of a set of 14 independent variables. While space limitations do not permit a full discussion of these results here, we note that the best predictors for these transitions were the distance to the closest village and population density. Average distance-to-closest-village distributions for four transition classes (barren to open vegetation, closed to open vegetation, forest to crop and forest to mixed crop, and natural vegetation) are shown in Figure 6. There is a clear tendency for transitions from forest-to-crop to occur near occupied areas and within regions with higher population densities. This proclivity, combined with demographic inertia of populations to continue to rapidly grow due to the large number of potential mothers present within the existing population (Bongaarts 1994), implies that most agricultural growth is likely to be coincident with areas that appear associated with drying tendencies.

2.16.3.5 Population Growth, Climate Gradients, and Future Food Security

Ethiopia's population of 90.9 million people expanded by 68% between 1990 and 2010 (or by 33 million people). According to Gridded Population of the World statistics (CIESEN 2011), most of these population increases occurred

in Oromia (+11 million people) and SNNPR (+6 million), densely populated areas where we have seen that rainfall has been rapidly declining (Figures 3 and 4), while the populations of chronically food insecure Somali, Tigray, and Afar regions have increased by ~1.5, 1.9, and 1.1 million people, respectively. Given that Ethiopia is a land-locked country that depends on rain-fed agricultural, agro-pastoral, and pastoral livelihoods, this population expansion will place increasing stress on limited natural resources. Crop statistics from the Food and Agriculture Organization of the United Nations show that per capita cereal production in Ethiopia is relatively low (150 kilograms per person per year). While yields have been improving, the amount of farmland per person has been declining at a rate twice as fast. If these trends persist, per capita cereal production could decline by 28% by 2025.

In order to meet its food needs and improve food security, Ethiopia will need to both improve its yields and continue expanding its agricultural area. Planning should take into account the relative security of the northwest and central highlands, where there are, and will be, large areas with low climatic crop risk. We can visualize the interaction of climate trends and Ethiopia's complex mean climate by examining transects of mean observed and projected rainfall. Figure 7 shows the observed 1960–89, observed 1990–2009, and projected 2010–39 June–September rainfall means at 8°N. This graphic indicates how the local climate can interact with terrain. In Ethiopia, rainfall tends to increase to the west and at higher elevations, and the interaction of these two features is seen in a rise, a decrease, and then another rise in rainfall when moving from east-to-west at 8°N. Population density in central Ethiopia tends to peak in the mountains and valleys of the

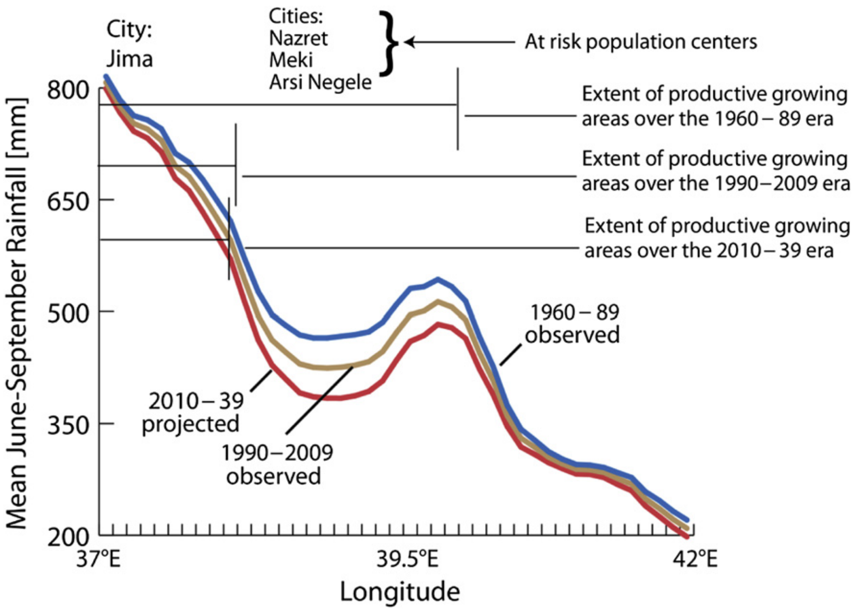

Figure 7 Transects of mean 1960–89 and 1990–2009 June–September rainfall, along with 2010–39 projected rainfall (transects taken along 8°N).

central Rift area. This area has already experienced substantial declines in *Kiremt* rains between 1960–89 and 1990–2009, and further declines seem likely. Population densities in this area (**Figure 2(c)**) are very high, and this area of Ethiopia appears to be an emergent area of increasing risk. In the areas surrounding cities like Nazret, Meki, and Arsi Negele, declining rainfall should be of great concern regarding the impacts it is having on the food security of these large populations (**Figure 3(b)**).

2.16.3.6 Livelihoods and Socioeconomic Analysis

Prior FEWS NET analysis by the Livelihoods Integration Unit (LIU 2010) provides a useful and interesting context for analyzing and discussing vulnerability patterns of climate and land use change. Drawing from extensive livelihood mapping surveys and Ethiopian socioeconomic data archives, the LIU has constructed a detailed Livelihoods Atlas. Of particular concern here is how the interaction of mean climate, climate variability, market access, road networks, and livelihoods shape the distribution of poverty and limit access to food and wages. As the Nobel Laureate and economist, Amatya Sen, pointed out in 1982, it is ultimately the limited access to food that creates famine (Sen, 1982). It is when food prices rise and food becomes too expensive that the poorest face starvation, malnutrition, and associated diseases. Such, for example, was the case in 2011, when marginalized and impoverished pastoralists in Ethiopia, Somalia, and Kenya faced rocketing food prices. We have also argued, however, that agricultural productivity, a major source of income, also plays an important role in food insecurity (Funk et al. 2008). A major determinant of household agricultural production is the amount of cultivated land per household (**Figure 8(a)**). Farm size plays an important role in determining the average food security of households, as measured in the average household income, expressed as a percentage of the annual household food needs (**Figure 8(b)**). Blue shades in this figure are used to map wealth within agricultural households; red shades are used to map pastoral wealth. There is a reasonable association between average household wealth and average farm size. Wealthier families tend to have more than two hectares of farmland. This does not appear to be the case in the south-central portion of the country (marked with a red box, 4–8°N, 37.75°–40°E),

Figure 8 Livelihood and socioeconomic information for Ethiopia. (a) Hectares of farmland per household. (b) Total income (food and cash) excluding aid by livelihood type of zone. (c) Cash income per Ethiopian Animal Income Unit. (d) Days of work required to buy one quintal of grain.

where we have noted substantial climate and land use changes. In this densely populated region (**Figure 1**) many households have less than one hectare per family of farmland and have typical incomes of less than 200% of their total family caloric needs. Small land holdings in poor climatic regions support chronic poverty. These fragile household food economies can be shattered by volatile food prices or failed rains.

Despite low access to markets, many households in south-central Ethiopia are nonetheless heavily dependent on purchased food (LIU 2010). The cost of food can be measured in terms of the cash income per Ethiopian Animal Income Unit (EAIU). This is a unit based upon an analysis of total income nationally derived from each species, EAIU calculation: 1 camel = 6 shoats; 1 cow/ox = 4 shoats. In the green areas of **Figure 8(c)**, demand is high, availability is low, and the relative cost of livestock is high. While some of these locations are associated with high incomes (**Figure 8(b)**), there are several regions where high food prices coincide with low incomes. South-central Ethiopia is one such region.

Labor can be another important source of revenue that alleviates food insecurity. **Figure 9(d)** shows the number of days of manual labor typically required to purchase a standard measure of grain in Ethiopia. The value of labor dramatically varies across the country. In some areas, "local workers may be many, the crop less valuable or labor-intensive, and grain expensive far from surplus markets" (LIU 2010). Wages in these regions, which are shown in deep blue in **Figure 8(d)** are "as low as they can be: the price of a day's food." Wages are typically very low across most of south-central Ethiopia.

Summarizing **Figure 8**, it appears that high vulnerability agricultural households in Ethiopia might be categorized as small land holdings (**Figure 8(a)**), low average total household incomes (**Figure 8(b)**), high average food prices (**Figure 8(c)**), and low average wages (**Figure 8(d)**). These problem areas are not limited to south-central Ethiopia and in fact many regions of north-central and north-eastern Ethiopia experience chronic and severe food insecurity. Nonetheless, the coincident expansion of agriculture and aridity across south-central Ethiopia appears likely to affect some very fragile food economies where the combined effects of poverty, high prices, and small farms sizes make development difficult.

2.16.4 Summary and Discussion

Our basic hypothesis is that East Africa is becoming drier due to an intensification of the climatological processes that make it dry to begin with. Gill (1980) showed that the tropical atmosphere forced by a steady source of diabatic heating produced an overturning circulation that resembled the observed Walker circulation. A stationary Rossby wave response to the west of the source of diabatic heating could increase subsidence over eastern Africa. While such a simple model masks the very complex factors that create East African weather, such behavior can be identified in both canonical correlation analyses of reanalysis fields and diabatic forcing modeling experiments that demonstrate a negative association between rainfall over the Indian Ocean and East Africa (Funk et al. 2008). More recent work has emphasized the joint warming of sea surface temperatures (SSTs) in both the Indian Ocean and western Pacific, suggesting that increases in Indo-Pacific Warm Pool convection can be understood as a spatial extension of the Warm Pool (Williams and Funk 2011). Williams and Funk (2012) emphasized the long-term trend in Warm Pool SSTs, rainfall, and winds, and the important interaction of this trend with interannual La Niña-like climate events. It has been recognized that an evaluation of trends plays an important part of early warning systems (Funk and Verdin 2009) and the new appreciation of La Niña's climate implications for the region helped trigger effective early warning of the 2011 East African food crisis (Ververs 2012; Funk, 2011). The more recent work of Lyon and Dewitt (2012) identified the exceptional warmth of the 1999–2011 period and used SST driven modeling experiments to demonstrate the important, and potentially dominant, role played by the western tropical Pacific. A recent evaluation of the new phase 5 coupled ocean–atmosphere model intercomparison project SST simulations (Funk 2012) prepared for the fifth Intergovernmental Panel on Climate Change assessment report indicates that this warming is almost perfectly predicted by the models solely driven with anthropogenic greenhouse gasses and aerosols, and exceptionally warm MAMJ SSTs ($\geq$28.7 °C) in the Indo-Western Pacific (15°S–15°N, 60°–170°E) have repeatedly occurred in the twenty first century (2001–2006, 2009–2012). It seems likely that western Pacific SSTs may dominate equatorial eastern Africa rainfall variations during boreal spring, while during boreal summer warming in the south-central Indian Ocean may tend to reduce rainfall across southwestern Ethiopia, southern Sudan, and northern Uganda (Williams et al. 2011).

The FTA strategy represents a relatively unique combination of top down and bottom up 'upscaling' and 'downscaling' (**Figure 1**). During the upscaling phase, terrestrial observations of rainfall are used to identify drought events, then large scale climate observations are evaluated, and then specific causal hypotheses are evaluated. Statistical evaluations and experiments with climate models can reinforce or weaken our confidence in specific causal factors. During the downscaling phase, evaluations of large scale climate tendencies are combined with interpolated station-based trend evaluations to produce projections of potential 2030 climate change. For example, since we believe that the recent observed drying trends across southern and southwestern Ethiopia are caused, at least in part, by large scale, long-term warming in the Indian and possibly western Pacific, it seems plausible to assume that drying trends may persist over the next few decades.

Our land cover analysis identified many transitions into cropland in the increasingly semiarid or arid south (**Figure 5**). Driven by population pressure, roads, and dense settlement patterns, this region is becoming more heavily cultivated. The intersection of rapid population growth, agricultural extensification, environmental degradation, and decreasing rainfall seems quite likely to result in increasing food and water security problems for this region.

This set of trends can be contrasted with conditions in the northwest of the country. Here, rainfall has been steady or increasing and the rate of cropland transitions and degradation is much lower than in the south. Extrapolated projections of 2010–39 average JJAS rainfall show that much of this region will very likely remain suitable for crop production. While developing the market, transport, and agricultural infrastructure to expand agriculture into these areas will prove a great challenge, national and international planning agencies should consider the relative climatic security of these regions as they formulate development plans. If Ethiopia could shift the center of its agricultural activity into regions of greater climatic security, its livelihoods would likely produce a much more reliable food supply and reduce its vulnerability. Investing in agricultural development, especially in areas that are currently climate secure areas, could also dramatically help improve production and lower price volatility. While the limited financial resources of poor agriculturalists make any progress difficult, Ethiopia's chronic and growing food insecurity could be addressed, at least in part, by vigorous and well planned development strategies. A thorough understanding of the local trends in land use, climate, and population should likely play a role in such planning.

Dr Roger A. Pielke is currently a senior research scientist in CIRES and a senior research associate at the University of Colorado-Boulder in the Department of Atmospheric and Oceanic Sciences (ATOC) at the University of Colorado in Boulder (November 2005—Present). He is also an emeritus professor of atmospheric science at Colorado State University and has a 5-year appointment (April 2007—March 2012) on the Graduate Faculty of Purdue University in West Lafayette, Indiana.

He has studied terrain-induced mesoscale systems, including the development of a three-dimensional mesoscale model of the sea breeze, for which he received the NOAA Distinguished Authorship Award for 1974. He has worked for NOAA's Experimental Meteorology Lab (1971—74), The University of Virginia (1974—81), and Colorado State University (1981—2006). He served as Colorado State Climatologist from 1999—2006. He was an adjunct faculty member in the Department of Civil and Environmental Engineering at Duke University in Durham, North Carolina (July 2003—06). He was a visiting professor in the Department of Atmospheric Sciences at the University of Arizona from October to December 2004.

He has served as chairman and member of the AMS Committee on Weather Forecasting and Analysis, and was the chief editor for the Monthly Weather Review for 5 years from 1981 to 1985. In 1977, he received the AMS Leroy Meisinger Award for ‘fundamental contributions to mesoscale meteorology through numerical modeling of the sea breeze and interaction among the mountains, oceans, boundary layer, and the free atmosphere’. He received the 1984 Abell New Faculty Research and Graduate Program Award, and also received the 1987/1988 Abell Research Faculty Award. He was declared ‘Researcher of the Year’ by the Colorado State University Research Foundation in 1993. In 2000, he received the Engineering Dean's Council Award from Colorado State University.

He authored a book published by Academic Press entitled ‘Mesoscale meteorological modeling’ in 1984 with a 2nd edition in 2002, a book for Routledge Press entitled ‘The Hurricane in 1990, a book (coauthored with W.R. Cotton) for Cambridge Press entitled ‘Human impacts on weather and climate in 1995; 2nd ed., 2006, a book (coauthored with R.A. Pielke, Jr.) entitled ‘Hurricanes: Their nature and impacts on society’ published in 1997 by John Wiley and Sons, and was co-chief editor (with R.A. Pielke, Jr.) of a book entitled ‘Storms’ published by Routledge Press in 1999.

He was elected as a fellow of the AMS in 1982 and fellow of the American Geophysical Union in 2004. From 1993—96, he served as editor-in-chief of the US National Science Report to the IUGG (1991—94) for the American Geophysical Union. From January 1996 to December 2000, he served as co-chief editor of the *Journal of Atmospheric Science*. In 1998, he received NOAA's ERL Outstanding Scientific Paper (with Conrad Ziegler and Tsengdar Lee) for a modeling study of the convective dryline. He was designated a Pennsylvania State Centennial Fellow in 1996, and named the Pennsylvania State College of Earth and Mineral Sciences Alumni of the year for 1999 (with Bill Cotton). He is currently serving on the AGU Focus Group on Natural Hazards (August 2009—Present) and the AMS Committee on Planned and Inadvertent Weather Modification (October 2009—Present). He is among one of three faculties and one of four members listed by ISI Highly Cited in Geosciences at Colorado State University and the University of Colorado at Boulder, respectively.

He has published over 370 papers in peer-reviewed journals, 55 chapters in books, coedited 9 books, and made over 700 presentations during his career to date. The listing of papers can be viewed at the project website: http://cires.colorado.edu/science/groups/pielke/pubs/. He also launched a science weblog in 2005 to discuss weather and climate issues. This weblog was named one of the 50 most popular Scienceblogs by Nature Magazine on 5 July 2006 and is located at http://pielkeclimatesci.wordpress.com/.

VOLUME EDITORS

Dr Jimmy Adegoke is an award winning climate scientist whose research focuses on understanding the relationships between changing land surface processes and diverse indicators of environmental change. His recent work focuses on societal impacts of environmental change including air pollution studies in rapidly changing midlatitude urban areas and climate impacts on water resources in the Lake Chad Basin. He teaches at the University of Missouri-Kansas City (UMKC) where he served as chair of the Department of Geosciences from 2008—10. From August 2010 until very recently, he was Executive Director of the Council for Scientific and Industrial Research (CSIR) Natural Resources and Environment (NRE) Division, Pretoria, South Africa where he also served as the Director of the Applied Center for Climate and Earth Systems Science (ACCESS), a Center of Excellence (CoE) of the South Africa Department of Science and Technology (DST) Global Change Grand Challenge (GCGC) program. He is a member of several professional societies including the American Geophysical Union (AGU), Association of American Geographers (AAG), and American Meteorological Society (AMS). He is on the advisory council of the African Association for Remote Sensing of the Environment (AARSE) and also serves on the technical advisory committee of several United Nations applied science programs, including the United Nations Educational Scientific and Cultural Organization (UNESCO) crosscutting project on the application of remote sensing for water resources and ecosystem management in Africa. He lives in Kansas city where he served a 3-year team as an appointee of the Mayor of Kansas City Missouri (KCMO) on the city's Environmental Management Commission (EMC).

Dr Caradee Y. Wright is a senior researcher at the Council for Scientific and Industrial Research in the Climate Studies, Modelling and Environmental Health Research Group, leading the environmental health research team. She holds a PhD in public health from the University of Otago and an MSocSc in geography and environmental management from the University of Natal. Her research focuses on personal solar ultraviolet radiation exposure, personal dosimetry, health risk assessment, and skin cancer prevention. Recently, she has also worked in the field of air quality and finding ways to integrate public health into air quality management. She also works in the broader field of environmental health, leading large epidemiological, cross-sectional community surveys to consider the impacts of environmental pollution on community health and appropriate interventions. She is cochair of the South African Young Academy of Science, a member of the Global Young Academy, a council member of the National Association for Clean Air, and founder of the Environmental Health Research Network. In 2012, she was named one of 200 top young South Africans for her efforts to establish a SunSmart Research Programme and Lab in South Africa.

Dr Dev Niyogi is an associate professor with joint appointment in the Departments of Agronomy and Earth, Atmospheric, and Planetary Science at Perdue University.

He is also the State Climatologist for Indiana and Director of the Indiana State Climate Office. His research seeks to advance the understanding of vegetation and land surface processes in environmental, weather forecasting, and climate analyses, using a combination of dynamical models and surface, satellite remote sensing, and multiscale analysis products.

His research deals with the understanding and representation of the effects of vegetation – land surface processes in environmental processes at different scales. He is one of the three invited, nonfederal representatives to the community modeling effort of the Weather Research and Forecast (WRF) model working group on Land Surface Models, and to the Federal Geophysical Data Commission (FGDC) Spatial Climate Working Group.

He has authored or coauthored 25 successful proposals for external grants totaling over $3M. He vertically integrates undergraduate, graduate, and postdoctoral researchers in his research and is very interdisciplinary in developing collaborative projects.

Dr George Kallos is a professor at the University of Athens, School of Physics, Division of Environmental Physics and Meteorology. He leads the Atmospheric Modeling and Weather Forecasting Group (AM & WFG). He has a BSc from the University of Athens/School of Mathematics (1975). He obtained his MSc (1983) and PhD (1985) in Geophysical Sciences/ Atmospheric Sciences Division, Georgia Institute of Technology, School of Geophysical Sciences, USA. He has 110 publications in peer review scientific journals, more than 230 presentations and publications in conference proceedings publications, 10 contributions in books and more than 200 other publications in subjects related to atmospheric physics and chemistry, sea-state conditions, and renewable energy production. He has been invited 70 times to give talks in conferences, seminars, etc. His published work has received >2000 citations. He has participated in 80 projects. He has organized 12 conferences related to air pollution and dust transport in the Mediterranean. He has supervised 10 PhDs and over 100 MSc theses and participated in 20 PhD examinations in Greece and Europe. He is an associate editor for the journals: '*Environmental Fluid Mechanics*', '*Advances in Meteorology*', '*International Journal of Geosciences*', '*Atmospheric Pollution Research*', and '*Journal of Aerospace Operations*'. He was awarded the International Union of Air Pollution Prevention Association – IUAPPA award for his work on 'Long-range transport and air quality work in the Mediterranean region'. His current research activities are related to atmospheric, climatic, air pollution, and sea-state model development and forecasting. He focuses in fully coupled modeling systems. The latest model developments are related to nucleation processes in clouds, desert dust cycle and its direct and indirect effects. Research activities related to renewable energy resources (wind, ocean, solar) are focusing on high accuracy atmospheric model development, energy relationships and predictions, and protection from extremes.

Timothy Seastedt received his BA in biology from the University of Montana, an MS degree in biological sciences from the University of Alaska at Fairbanks, and a PhD degree from the University of Georgia. He was on the faculty at Kansas State University and is currently a professor of Ecology and Evolutionary Biology and fellow of INSTAAR at the University of Colorado, Boulder. Much of his research has been conducted as part of the Long-Term Ecological Research (LTER) programs at KSU and CU. His interests focus on terrestrial ecosystem ecology and the causes and consequences of biotic change. His recent activities have emphasized the ongoing changes found along the grassland to (melting) glacier gradient that exists in the Colorado Front Range.

Katharine Suding received her BA in biology from Williams College and a PhD degree from the University of Michigan. She was on the faculty at University of California Irvine and is currently a professor in Environmental Science, Policy and Management at the University of California Berkeley. Her background is in plant community and ecosystem ecology, with current interests in restoration, resilience, and environmental change.

Faisal Hossain received his PhD from the University of Connecticut in 2004. Prior to that, he had earned his MS and BS from the National University of Singapore and Indian Institute of Technology, Varanasi, respectively. He is currently an associate professor in the Department of Civil and Environmental Engineering where he received one of the highest awards of University – the Caplenor Research Award in 2012. His research interests comprise hydrologic remote sensing, uncertainty modeling of water cycle variables, human modification of extreme hydro-climatology, sustainable water resources engineering, space-borne transboundary water resources management, engineering education, and public outreach. He is also the recipient of awards such as NASA Earth System Science Fellowship (2002), Outstanding PhD Thesis Award (2005), NASA New Investigator Award (2008), American Society of Engineering Education (ASEE) Outstanding Research Award (2009), National Association of Environmental Professionals Education Excellence Award (2010), US Fulbright Faculty Award (2012), G.O.L.D. (Graduate Of the Last Decade) award from University of Connecticut (2012), and American Geophysical Union (AGU) Charles Falkenberg Award. He has published over 85 peer-reviewed journal articles, authored an undergraduate-level textbook, edited two book volumes, and contributed eight book chapters. His recent research on human modification of extreme events by artificial reservoirs has been featured by public media such as the BBC, National Geographic, New Scientist, Newsweek, Fox News, MSNBC, Wired.com, and German Public Radio. He served as an associate editor of *Journal of American Water Resources Association* from 2006–10. Currently, he serves as an associate editor for *Journal of Hydrometeorology* and a lead editor for the water volume of Elsevier Sciences five volume reference series on '*Climate Vulnerability: Understanding and Addressing Threats to Essential Resources*'.

PREFACE

We are pleased to introduce the five-volume set of books on bottom-up, resource-based vulnerability assessments of the societally and environmentally key resources of water, food, energy, human health and well-being, and ecosystem function. This inclusive bottom-up vulnerability concept requires the determination of the major threats to these resources from climate, but also from other social and environmental issues. After these threats are identified for each resource, the relative risk from natural- and human-caused climate change (estimated from global climate model (GCM) projections, as well as the historical, paleorecord, and worst case sequences of events) can be compared with other environmental and social risks in order to adopt the optimal mitigation and adaptation strategies.

The bottom-up, resource-based approach (referred to by O'Brien (2009) as 'contextual vulnerability') that is the focus of the volume is distinct from the Intergovernmental Panel on Climate Change (IPCC) top-down assessment of vulnerability based on the multidecadal GCM predictions (projections) which O'Brien defined as 'outcome vulnerability' (**Table 1** and **Figure 1**).

An excellent example of the contextual vulnerability is the paper by Romero-Lankao et al. (2012) who concluded in a study of the literature that urban vulnerability is dominated by epidemiological studies and top-down assessments, but that inherent urban vulnerability and urban resilience approaches (the contextual vulnerability) are what is required in order to illuminate a more complete set of drivers of urban vulnerability. They also showed that the large majority of papers on vulnerability use the outcome vulnerability approach. However, as discussed below, this top-down approach has major flaws.

First, there is the issue that the term 'climate' has two definitions. The broader view (and the one adopted by NRC (2005)) is that climate consists of the atmosphere, oceans, land, and cryosphere. This is the preferred usage. The second definition is that climate is the term used for the long-term (e.g., multidecadal) statistics of weather.

As reported in the NRC (2005) report and written in the Pielke et al. (2009) article with respect to human climate forcings.

> In addition to greenhouse gas emissions, other first-order human climate forcings are important to understanding the future behavior of Earth's climate. These forcings are spatially heterogeneous and include the effect of aerosols on clouds and associated precipitation [e.g., Rosenfeld et al. 2008], the influence of aerosol deposition (e.g., black carbon (soot) [Flanner et al. 2007] and reactive nitrogen [Galloway et al. 2004]), and the role of changes in land use/land cover [e.g., Takata et al. 2009]. Among their effects is their role in altering atmospheric and ocean circulation features away from what they would be in the natural climate system [NRC 2005]. As with CO_2, the lengths of time that they affect the climate are estimated to be on multidecadal timescales and longer.

and

> "…the natural causes of climate variations and changes are important, as are the human influences. The human climate forcings involve a diverse range of first-order climate forcings, including, but not limited to, the human input of carbon dioxide (CO2). Most, if not all, of these human influences on regional and global climate will continue to be of concern during the coming decades."

Threats from climate involve any one or combination of climate variables as illustrated in **Figure 2**. There do not, of course, have to be changes in the statistics of these variables to constitute a risk. The term

Table 1 Contrast between a top-down versus bottom-up assessment of the vulnerability of resources to climate variability and change

Approach	*Comparative vulnerability*	*Contextual vulnerability*
Assumed dominant stress	Climate, recent greenhouse gas emissions to the atmosphere, ocean temperatures, aerosols, etc.	Multiple stresses: climate (historical climate variability, land use and water use, altered disturbance regimes, invasive species, contaminants/pollutants, habitat loss, etc.)
Usual timeframe of concern	Long-term, doubled CO_2 30–100 years in the future.	Short-term (0–30 years) and long-term research.
Usual scale of concern	Global, sometimes regional. Local scale needs downscaling techniques. However, there is little evidence to suggest that present models provide realistic, accurate, or precise climate scenarios at local or regional scales.	Local, regional, national, and global scales.
Major parameters of concern	Spatially averaged changes in mean temperatures and precipitation in fairly large grid cells with some regional scenarios for drought.	Potential extreme values in multiple parameters (temperature, precipitations, frost-free days) and additional focus on extreme events (floods, fires, droughts, etc.) measures of uncertainty.
Major limitations for developing coping strategies	Focus on single stress limits preparedness for other stresses. Results often show gradual ramping of climate change-limiting preparedness for extreme events. Results represent only a limited subset of all likely future outcomes – usually unidirectional trends. Results are accepted by many scientists, the media, and the public as actual 'predictions'. Lost in the translation of results is that all models of the distant future have unstated (presently unknowable) levels of certainty or probability.	Approach requires detailed data on multiple stresses and their interactions at local, regional, national, and global scales, and many areas lack adequate information. Emphasis on short-term issues may limit preparedness for abrupt "threshold" changes in climate sometime in the short or long term. Requires preparedness for a far greater variation of possible futures, including abrupt changes in any direction – this is probably more realistic, yet difficult.

Adapted from Kabat et al. 2004.

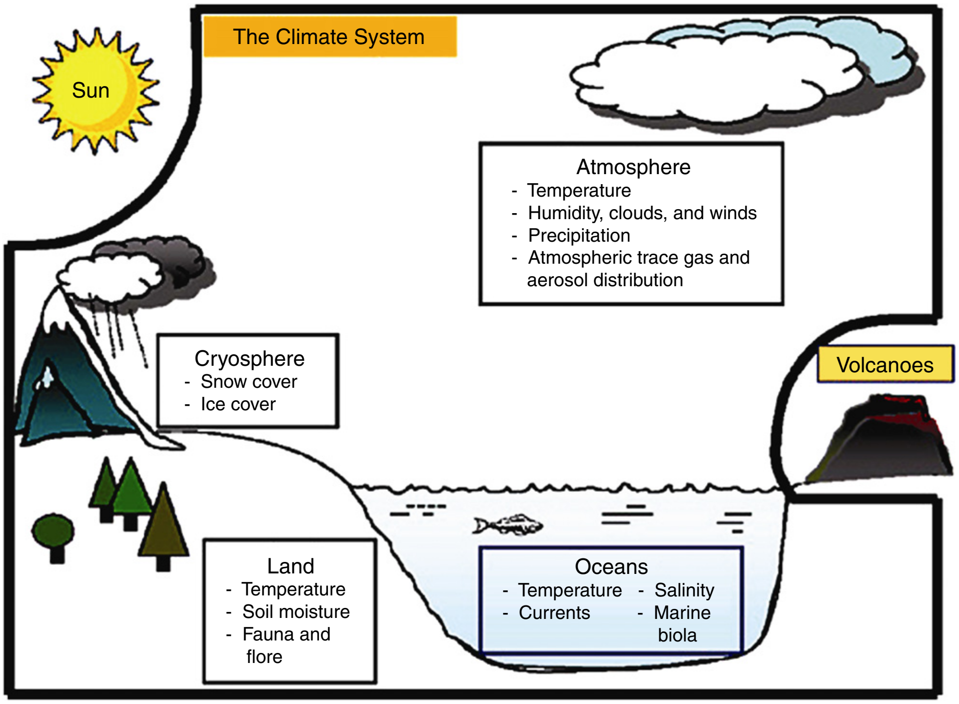
Figure 1 Framework depicting two interpretations of vulnerability to climate change: (a) outcome vulnerability and (b) contextual vulnerability. *From: Füssel (2009) and O'Brien et al. (2007).*

'climate change' should be used to describe any multidecadal or longer alteration in one or more physical, chemical, and/or biological components of the climate system, but as explained below, this terminology has morphed into multiple, diverse (and often mutually exclusive) definitions as used by the impacts communities.



The Climate System
Sun
Atmosphere
- Temperature
- Humidity, clouds, and winds
- Precipitation
- Atmospheric trace gas and aerosol distribution
Cryosphere
- Snow cover
- Ice cover
Volcanoes
Land
- Temperature
- Soil moisture
- Fauna and flore
Oceans
- Temperature
- Currents
- Salinity
- Marine biola

Figure 2 The climate system, consisting of the atmosphere, oceans, land, and cryosphere. Important state variables for each sphere of the climate system are listed in the boxes. For the purposes of this report, the Sun, volcanic emissions, and human-caused emissions of greenhouse gases and changes to the land surface are considered external to the climate system (NRC 2005).

First, climate is never static (Lovejoy and Schertzer 2012). As written in Rial et al. (2004)

> "The Earth's climate system is highly nonlinear: inputs and outputs are not proportional, change is often episodic and abrupt, rather than slow and gradual, and multiple equilibria are the norm."

The assumption of a stable climate system (e.g., the reason for the use of the terminology 'climate stabilization') in the absence of human intervention is a mischaracterization of the behavior of the real climate system. Humans are now adding to the complexity of forcings and feedbacks, but change has always been a part of the climate system. 'Climate change' is, and always has, been occurring. The added word 'change' is, therefore, redundant.

Moreover, there are additional misunderstandings. 'Global warming', which is an increase in the global annual average heat content measured in Joules, is often incorrectly equated to mean 'climate change'. Global warming, however, is just a subset of "climate change."

The term 'climate change', is also being erroneously used to mean only 'anthropogenic caused changes in climate' from nearly 'static' climatic conditions. Frequently, just the human input of greenhouse gases is assumed to be the reason for 'climate change'. For example, NRC (2010) (Climate Stabilization Targets: Emissions, Concentrations, and Impacts Over Decades to Millennia (2010)) states

> "This new report from the National Research Council concludes that emissions of carbon dioxide from the burning of fossil fuels have ushered in a new epoch where human activities will largely determine the evolution of Earth's climate."

Thus, the recommendations to the authors of the volume (not always accepted) were to replace terminology, such as climate change, climate stabilization, and climate disruption, with accurate terminology. When changes in climatic conditions are discussed, it was requested that the actual climate variables (such as temperature, precipitation, length of growing season) that are being altered, be specified. Phrases such as 'changes in regional and global climate statistics' could also be used.

There is a very fundamental reason to limit the use of 'climate change' by the impacts community. Key societal and environmental resources, such as water, food, energy, ecosystem function, and human health respond to climate, not just to an incremental change in the climatic conditions. As noted earlier, the assumption of a stable climate system, in the absence of human intervention, is a mischaracterization of the behavior of the real climate system.

However, some authors retained the use of the terminology 'climate change'. It was acquiesced as long as there was a significant contribution in their chapter to a broad-based assessment of risk to the key resource they were discussing.

Another misused term is 'global change', when really what is almost always meant is a local and/or regional change in the environmental conditions, including from climate. The accurate terminology should be 'environmental change'. The term 'environmental change' is, therefore, preferred rather than 'global change', as the latter terminology is very much a top-down viewpoint. Almost all impacts on key resources are on the local and regional scale.

We also requested the authors start with the risks and factor in the climate threats after thresholds, etc. were first obtained. This was not done in some chapters, but this information can still be extracted from the text. Obtaining the spectrum of risks first is the more inclusive way to assess threats to key resources, and thus, in the view, to prepare the optimal mitigation and adaptation strategies.

For the climate component of risk, the outcome vulnerability (the top-down) approach relies on skillful weather predictions and analyzes with a regional and a local focus. For weather prediction on time periods of days to a week or two, excellent skillful predictions are available for use in outcome vulnerability assessments. On seasonal timescales, there is also some limited predictive skill to apply to outcome vulnerability assessments, particularly for such well-defined weather events such as an El Niño or La Niña (Castro et al. 2007). However, for decadal and multidecadal predictions little, if any, predictive skill has been shown in hindcast climate model predictions of changes in regional weather statistics beyond what is available to the impacts community via the historical, recent paleorecord and a worst case sequence of weather events.

To illustrate the lack of skill, the conclusions from several papers have been summarized. Fyfe et al. (2011) concluded that

> "….for longer term decadal hindcasts a linear trend correction may be required if the model does not reproduce long-term trends. For this reason, we correct for systematic long-term trend biases."

Xu and Yang (2012) find that without tuning from real world observations, the model predictions are in significant error. For example, they found that

> …the traditional dynamic downscaling (TDD) [i.e. without tuning) overestimates precipitation by 0.5-1.5 mm d-1…..The 2-year return level of summer daily maximum temperature simulated by the TDD is underestimated by 2-6°C over the central United States-Canada region."

The paper van Oldenborgh et al. (2012) report just limited predictive skill in two regions of the oceans on the decadal time period, but no regional skill elsewhere, when they conclude that:

> "A 4-model 12-member ensemble of 10-yr hindcasts has been analysed for skill in SST, 2m temperature and precipitation. The main source of skill in temperature is the trend, which is primarily forced by greenhouse gases and aerosols. This trend contributes almost everywhere to the skill. Variation in the global mean temperature around the trend does not have any skill beyond the first year. However, regionally there appears to be skill beyond the trend in the two areas of well-known low-frequency variability: SST in parts of the North Atlantic and Pacific Oceans is predicted better than persistence. A comparison with the CMIP3 ensemble shows that the skill in the northern North Atlantic and eastern Pacific is most likely due to the initialisation, whereas the skill in the subtropical North Atlantic and western North Pacific are probably due to the forcing."

Anagnostopoulos et al. (2010) report that

> "…. local projections do not correlate well with observed measurements. Furthermore, we found that the correlation at a large spatial scale, i.e. the contiguous USA, is worse than [even] at the local scale."

Stephens et al. (2010) wrote

> "models produce precipitation approximately twice as often as that observed and make rainfall far too lightly…..The differences in the character of model precipitation are systemic and have a number of important implications for modeling the coupled Earth system …….little skill in precipitation [is] calculated at individual grid points, and thus applications involving downscaling of grid point precipitation to yet even finer-scale resolution has little foundation and relevance to the real Earth system."

van Haren et al. (2012) concluded from their study with respect to climate model predictions of precipitation that

> "An investigation of precipitation trends in two multi-model ensembles including both global and regional climate models shows that these models fail to reproduce the observed trends….. A quantitative understanding of the causes of these trends is needed so that climate model based projections of future climate can be corrected for these precipitation trend biases…. To conclude, modeled atmospheric circulation and SST trends over the past century are significantly different from the observed ones."

Sun et al. (2012) found that

> "…in global climate models, [t]he radiation sampling error due to infrequent radiation calculations is investigated …….. It is found that…. errors are very large, exceeding 800 W m^{-2} at many non-radiation time steps due to ignoring the effects of clouds…."

There is an important summary of the limitations in multidecadal regional climate predictions in Kundzewicz and Stakhiv (2010) who succinctly conclude that

> "Simply put, the current suite of climate models were not developed to provide the level of accuracy required for adaptation-type analysis."

Since the top-down outcome vulnerability approach depends on skillful decadal and longer regional and local climate predictions, yet they have shown little if any skill, another approach is needed.

For this reason, the volume set of five books presents an alternate approach — the bottom-up, resource-based outcome (contextual) vulnerability perspective. The goal of the set was to focus on the climate component of stress but also consider, in-depth, other environmental and social threats.

The text of the articles is written at a level that allows undergraduate students to understand the material, while providing active researchers with a ready reference resource for information in the respective field.

The questions requested to the authors address with respect to a specific resource were:

1. Why is this resource important? How is it used? To what stakeholders is it valuable?
2. What are the key environmental and social variables that influence this resource?
3. What is the sensitivity of this resource to changes in each of these key variables? This includes, but is not limited to, the sensitivity of the resource to climate variations and change on short (e.g., days), medium (e.g., seasons), and long (e.g., multidecadal) timescales.
4. What changes (thresholds) in these key variables would have to occur to result in a negative (or positive) response to this resource?
5. What are the best estimates of the probabilities for these changes to occur? What tools are available to quantify the effect of these changes? Can these estimates be skillfully predicted?
6. What actions (adaptation/mitigation) can be undertaken in order to minimize or eliminate the negative consequences of these changes (or to optimize a positive response)?
7. What are specific recommendations for policymakers and other stakeholders?

There are also overview chapters that discuss the science of the resource.

Several authors insisted on focusing on the use of the outcome vulnerability (top-down) approach based on the multidecadal GCM projections (statistically or dynamically downscaled) as the starting point of their chapters. The chapters were accepted, despite this shortcoming, because when they finally discussed adaptation in their text, they did present the broader-based bottom-up focus that is the centerpiece of the volume. Readers,

however, need to be aware that the top-down, GCM scenarios are only a subset, at best, of what is plausible in the coming decades. Multidecadal predictions of changes in regional and local climate statistics have not shown skill when run in a hindcast mode for the past several decades.

In summary, the goal of the five-volume set of books is to document the value of a bottom-up, resource-based assessment of risk to key resources, as illustrated schematically in Figure 3a–e. Most, but not all, authors accepted this framework. This can be assessed without having any predictability on

Figure 3d Contextual vulnerability for human health and well-being (Adegoke and Wright Editors).

multidecadal time periods. It is an alternative (and more inclusive) perspective than the IPCC top-down outcome vulnerability approach which starts with the GCMs as the overarching framework. In the bottom-up approach, the scenarios from the GCM predictions should only enter after the specific threats to the resources are determined and even then, they provide, at best, a limited set of insights into what is possible.

Preface - Vulnerability of Energy to Climate

G Kallos, School of Physics, University of Athens, Athens, Greece

© 2013 Elsevier Inc. All rights reserved.

Water and therefore water resources can be considered of great importance for this planet; however, energy and energy resources are also recognized as paramount for maintaining life. Since the appearance of life on Earth, energy resources have been of crucial significance. Fire was the primary energy resource that changed the life of the first people on Earth. Energy resources were different through the centuries, but their resources were always vulnerable to different factors, and control of these resources was always a major issue. Energy resources may vary over time, but always remain vulnerable because of human activities and/or natural causes. For example, wood was a major source for maintaining fire for various human activities. Extended fires resulting from human intervention or natural activities (e.g., lightning) cleared large areas and forced the population to migrate, causing tensions with other tribes. Elemental energy resources (mainly wood) were more vulnerable in arid and semiarid regions of the planet because of the slow growth of vegetation and limited water availability. The use of fossil fuel as an energy resource during the preindustrial period was limited mainly to metal processing.

During the industrial era, energy resources became more and more important for sustainability and growth. The new energy resources also became more vulnerable to natural and mainly to human intervention. The most well-known new energy resources used during the industrial period were fossil fuels, mainly coal and oil. Exploitation of these energy resources had several consequences to the environment and society. Extraction and use of this energy required more and more complicated technology; therefore, vulnerability to disruption increased.

Several things changed concerning energy resources and their vulnerability after the invention of electricity and its use in homes and industry. Electrical networks, as well as oil and gas pipeline networks, became complicated, and transmission lines became more vulnerable to extreme weather events and other natural hazards (e.g., blackouts in California).

A major energy resource was added during the second half of the twentieth century – nuclear energy. Nuclear energy is vulnerable to a series of natural hazards such as extreme weather events, seismic activity, and tsunamis. (Note the recent event in Fukushima, Japan.)

Currently, renewable energy resources occupy more and more of the energy portfolio, with wind being the major source, followed by solar and biomass. Ocean energy occurs in different forms, but wave, tidal, sea current, and biomass growth are the most important ones. Ocean energy is currently only in an experimental phase, but is a promising energy resource for the future. Large ocean platforms for energy production are facing serious problems associated with extreme weather events and technological limitations. Renewable energy resources are vulnerable mainly to extreme weather and less to climate fluctuations.

Energy resources and distribution networks are controlled and managed by established markets. Today's markets have become complicated, and to a certain degree control the economic activities of the entire planet. Market vulnerability results from several factors, such as geopolitical tensions, financial perturbations, extreme weather events, and of course long-term climatic variability.

This volume covers important issues of various energy resources and discusses vulnerability issues. As in the other volumes of this climate encyclopedia, the bottom-up approach has been adopted. This approach is considered the most appropriate for decision making or adaptation compared with the top-down, outcome-oriented approach widely used in vulnerability studies.

This book volume aims to ask some basic questions which include the following:

- What are the key issues related to different kinds of energy resources?
- What are the major threats to these resources, and how vulnerable are they?
- What are the most important factors that affect energy vulnerability?
- How vulnerable are energy resources and their distribution networks to weather and climate?
- What do we have to do to maintain sustainability through the rational use of energy resources, with a special focus on those that are limited?

The volume is divided into four major sections. The first deals with energy, environment, and climate issues; the second with the vulnerability of various energy resources such as fossil fuels, nuclear energy, renewable, and hydropower; the third deals with energy production, conversion, transmission, distribution, policy, planning, and mitigation processes; and the fourth discusses networks and markets. The reader will find general information, although highly technical information is included in some chapters.

Thanks to all the contributing authors for the dedicated work they have collected and discussed in this volume. I hope the readers will find it a unique source of information.

Glossary

Air basin An area with a geographical structure or climatic condition that results in relatively little movement of air in or out of the area.

General circulation models (GCM) A mathematical model of the general circulation of a planetary atmosphere or ocean. It is based on the Navier–Stokes equations on a rotating sphere with thermodynamic terms for various energy sources (radiation, latent heat).

Greenhouse gas (GHG) A gas in an atmosphere that absorbs and emits radiation within the thermal infrared range.

Northeast corridor (NEC) A region consisting of Pennsylvania, New Jersey, New York, Vermont, Connecticut, Massachusetts, Delaware, New Hampshire, Maine, and the District of Columbia.

Southern California Air Basin (SoCAB) One of several geopolitical areas designed by the state of California for the purpose of air quality management. Includes all of Orange County and Los Angeles County and the nondesert regions of Riverside County and San Bernardino County.

The Special Report on Emissions Scenarios (SRES) A report by the Intergovernmental Panel on Climate Change (IPCC) that was published in 2000. The greenhouse gas emissions scenarios described in the report have been used to make projections of possible future climate change.

Statistical significance: In statistics, a result is called "statistically significant" at a given probability if it is unlikely to have occurred by chance at that level of probability.

Upwelling An oceanographic phenomenon that involves wind-driven motion of dense, cooler, and usually nutrient-rich water toward the ocean surface, replacing the warmer, usually nutrient-depleted surface water.

Urban heat island (UHI) An excess warmth of a metropolitan area over its surrounding rural areas. The main cause of the urban heat island is modification of the land surface by urban development which uses materials that effectively retain heat.

3.01.1 Introduction

Energy infrastructure and activity may be one of the most sensitive aspects of society to a climate in terms of demands, availability, and vulnerability. Climate defines, to a large degree, human comfort levels for space heating and cooling, and these demands are manifested differently in geographical locations. A warming climate may represent increased energy demands in tropical regions or decreased energy demands under winter conditions in high latitude regions. Climate trends may also represent high risk factors to the energy infrastructure when exposed to frequent and extended extreme

http://dx.doi.org/10.1016/B978-0-12-384703-4.00302-6

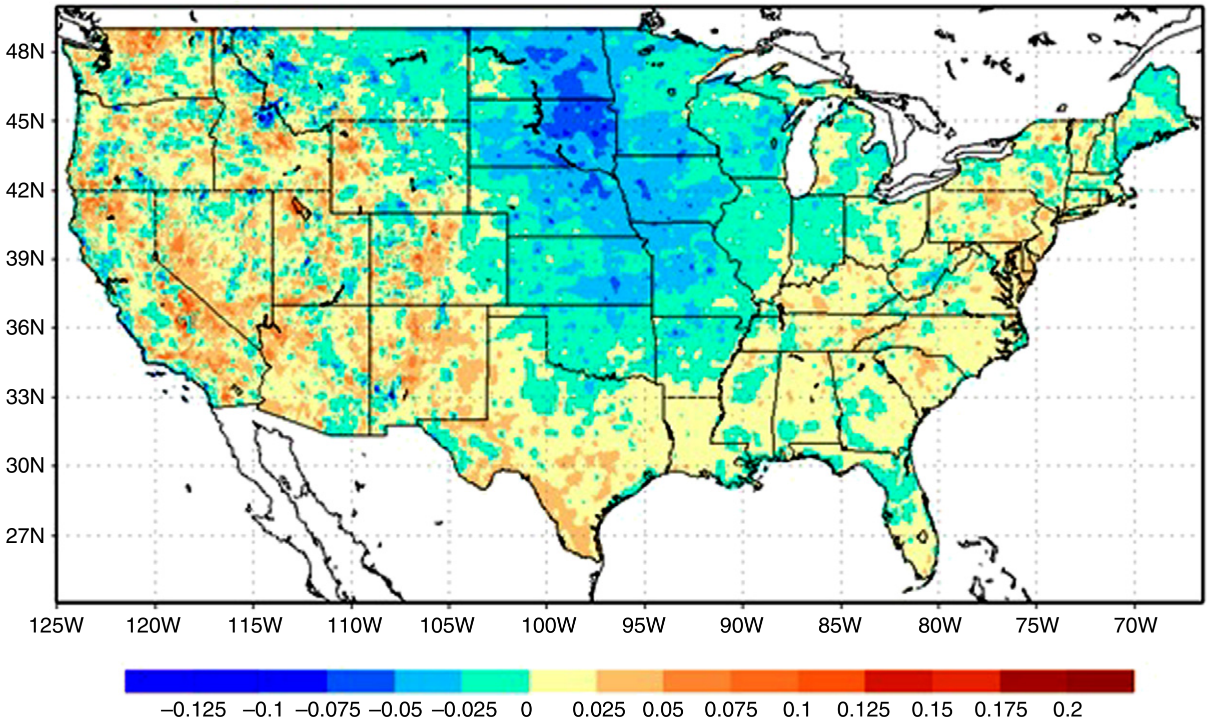

Figure 1 JJA Prism (4 km resolution) maximum-temperature trends for the period of 1970–2010 (°C decade^{-1}).

conditions such as heat waves or winter storms. This chapter focuses on reviewing and analyzing the connections between climate trends and energy for the case of the coastal regions of the United States. Coastal regions represent an interesting case characterized by high population, sensitivity to climate trends, and as will be seen in this chapter, results that seem to contradict ones anticipated common sense.

We will start with the fact that the climate is changing, as reflected in previous chapters of this book. This fact is again emphasized in Figures 1 and 2 (The PRISM Climate Group 2012), which show the trends of extreme surface temperatures, maximum and minimum, for the continental United States. We may expect that given the almost uniform warming trend of minimum temperatures, energy demands for heating may be reducing, with contrasting expectations for summer conditions. These general patterns and expectations may be correct in the overall context of total energy trends, as shown in Figure 3 (EIA 2011; U.S. Census 2009), which clearly shows an increasing trend in overall US electrical energy consumption and a reduction in natural gas consumption. The fundamental question of how precisely climate influences these trends is still unanswered. Figure 1 shows some exceptions from maximum-temperature trends, such as coastal California, where maximum temperatures have a decreasing trend. The specific question of connections between climate and energy in these regional scales should also be of major interest to the reader. The spatial distribution of total energy (both electricity and gas; Figures 4 and 5) suggests, in general, a correlation between reduced energy for space heating and increasing maximum temperatures; however, this is not clearly evident with trends on total electricity. Figure 4 shows overall increases in electricity for all states, with reduced increases in the Western Pacific and in other Northeastern coastal regions.

This chapter looks in-depth at the question of nexus between energy and climate trends by presenting an analysis and methodology for the US coastal areas of California and the Northeast Corridor region, including surface temperature trends, extreme events, spatial and temporal energy trends on a per sector basis, and possible reflections on CO_2 production. The presented methodology can be applied to almost any location around the globe.

3.01.2 Energy Trends in California

Energy activity is linked to climate trends in several ways. From the demand side, energy for space heating and cooling in buildings directly correlates to variability of surface temperature and humidity conditions. Buildings in general consume more than 30% of overall energy in the United States (Kreider et al. 2010). The relationship between energy and climate variability is investigated in detail for California and reported in this section. The analysis first considers degree-day analysis, followed by energy trends in demand sectors impacted by climate, including extremes.

3.01.2.1 Relationship between Energy and Climate in Coastal California

Degree-day analysis is the simplest method used for energy studies and is appropriate if energy used in buildings represents a significant component of the total energy budget (ASHRAE,

2005). Although computers can easily calculate the energy consumption of buildings, the concept of degree-days remains a valuable tool since a climate's severity can be concisely characterized in terms of degree-days. Also, the degree-day method and its generalizations can provide a simple estimate of annual loads. Such estimates can be accurate if the indoor temperature and internal gains are relatively constant and if the heating or cooling systems operate for a complete season (ASHRAE, 2005).

In a general sense, degree-day analyses estimate the increase or decrease in temperature needed for a building using a base temperature (T_{base}) and defined as the temperature at which a building reaches thermal equilibrium with the incoming energy and the environment. In this study, the T_{base} is assumed to be 18 °C, which represents average steady-state conditions in typical buildings. Summer hot days require the use of energy for cooling, as measured in Cooling Degree Day (CDD) values, while winter heating requirements are measured in Heating Degree Day (HDD) values.

To compute CDD or HDD values, the average temperature for a day (T_{day}) is estimated and T_{base} is subtracted; if the difference is positive, the day is a CDD, and if negative it is an HDD, as follows:

$$\text{CDD or HDD} = \sum_{1}^{n} (T_{\text{day}} - T_{\text{base}})$$

where n is the number of days in the month. The sum of all daily CDD and HDD values is the total monthly CDD and HDD value. In this study, T_{day} is assumed to be the average between the values of daily $T_{\max}$ and $T_{\min}$.

Many studies have used CDDs and HDDs from average-temperature data. Thom analyzed climatological degree-day (DD) trends with an empirical truncation coefficient related to

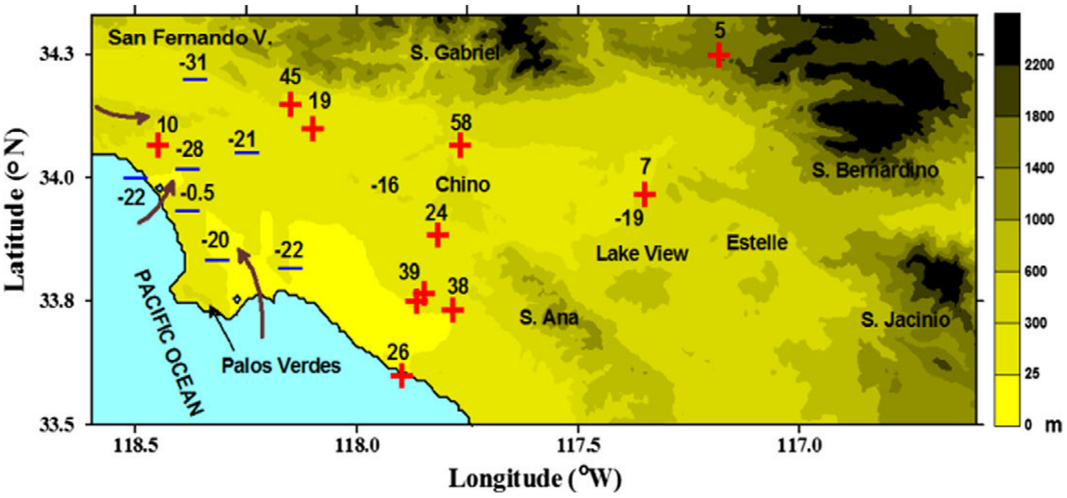

Figure 6 Spatial distributions of 1970–2005 summer CDD trends (DD decade^{-1}, where red pluses show increasing values and blue dashes show decreasing values) for the SoCAB (Lebassi et al. 2010).

monthly DD values. Thom analyzed the relationship between mean monthly DDs below a T_{base} of 18 °C and mean monthly temperatures by deriving probability functions of DD from probability functions of temperatures (Thom 1952). He later extended this by use of an unmodified truncation coefficient for any base temperature by modifying the truncation coefficient (Thom 1954, 1966). Downton et al. (1988) analyzed the National Climatic Data Center (NCDC) annual DD data from 1895 to 1983 and they found that historical population shifts affect US energy demands for cooling and heating. Quayle and Diaz (1980) used electric and fuel consumption data for individual residences, performed a regression analysis relating energy consumption and HDD totals, and concluded that short-term energy projections can be generated from accurate weather predictions. Diaz and Holle (1984) further analyzed the census data from 48 US states and studied the impact of population shifts from cooler-wetter regions to hotter-drier regions, which resulted in relatively lower heating needs but larger cooling needs nationwide. Most recently, Kolokotroni et al. (2010) using HDDs and Cooling Degree Hours (CDHs) developed a method for predicting air temperatures within the Urban Heat Island (UHI), which is a very reliable tool for use as part of the process of predicting heating and cooling loads for urban buildings.

Other studies have focused on impacts from climate change on the energy sector in California. Other works (Miller et al. 2008; Franco and Sanstad 2008; Franco 2005; Edwards, 1991; Darmstadter 1993; CEC 2006; Baxter and Calandri 1992) have reported energy-demand increases due to Greenhouse gas (GHG) warming, in general, and increases in summertime electricity consumption to create comfortable temperatures in indoor spaces.

A similar analysis was performed for the CDD and HDD values at the two California air basins previously discussed (Lebassi et al. 2010). Using daily data from Cooperative (COOP) stations, this analysis considered spatial trend distributions for 1970–2005 June–July–August CDD and December–January–February HDD values at the two air basins. The following analysis expands the study of the two California air basins to the whole state of California.

Results in the Southern California Air Basin (SoCAB) (Figure 6) show that most low-elevation coastal sites in the area have decreasing June–July–August CDD values consistent with falling average temperatures, while most inland and high-elevation stations show even larger increases consistent with GHG warming. Since the topography is much more complex in the San Francisco Bay Area (SFBA) and Central valley regions, so is its June–July–August CDD pattern. Only the areas that are open to marine air penetration through sea-level gaps and splits show decreasing CDD values; on the other hand, most high-elevation coastal sites, as well as inland sites and areas where the coastal mountains have blocked the sea breeze, show increasing values (Figure 7). The winter HDD trends are far more obvious than the summer CDD trends since marine influences are weaker during the winter and GHG warming features are dominant during that season. This is reflected in consistent decreasing HDD values in the majority of the locations in both air basins (Figures 8 and 9), which translates into warming winters.

Extended analyses for the rest of the state indicate that the same patterns are observed in the entire state and not only in the two air basins. Figure 10 shows that most of the cooling summer CDD trends are located in a narrow strip along the coast with a width of approximately 70 km as well as most low-elevation coastal sites. On the other hand, Figure 11 indicates the decreasing winter HDD trends all over the state except for a few isolated points, reflecting a warmer winter in the entire region during the past four decades. The implications of these trends in DD in actual energy demands are discussed in the following subsections.

2009, 2010; LaDochy et al. 2007; Cordero et al. 2011), actual energy demand studies have been restricted by short-term (Aroonruengsawat and Auffhammer 2009) and site-specific data availability (Miller et al. 2008; Franco and Sanstad 2008; Sequera et al. 2011). In order to ascertain long-term energy consumption trends across California, an analysis was undertaken using county-level monthly and yearly data from the California Energy Commission (CEC). These data were used to analyze spatial and temporal trends. Given the importance of understanding temperature–energy relationships in the context of global warming, this section focuses on actual energy consumption trends in coastal and inland California. An understanding of energy consumption behaviors at this spatial scale is important because statewide energy demands can be influenced by high population densities along the California coast, as shown in Figure 12 (U.S. Census Bureau 2011). Simple plots show that electric power consumption per person peaks during the summer time for coastal counties, inland counties, Sacramento County (located inland), and San Diego County, located along the coast. Moreover, the data show that electric power consumption per person appeared to increase from 1990 to 2009 for most

counties. In contrast, the data show that natural gas consumption per person appeared to decrease from 1990 to 2009 for most counties.

3.01.2.2.2 Data and Methods

County-level energy consumption data were obtained from the CEC. Electric power and natural gas consumption data were available for two temporal scales, monthly and yearly. Monthly data consisted of energy consumption estimates from 2005 to 2007. Yearly data consisted of residential and nonresidential energy actual consumption from 1990 to 2009. Both monthly and yearly residential electric power and natural gas values were normalized by population figures (U.S. Census Bureau 2011).

3,100,001–10,000,000

Figure 12 California census 2010 population by county (U.S. Census Bureau 2011).

Data from the CEC were used to create several graphs and maps. First, for the electric power consumption analysis, counties were divided into two categories: coastal and inland. For simplification, coastal counties included those in the western boundary that met the Pacific Ocean. Therefore, out of 58 counties, 15 were considered coastal while 43 were considered inland. Graphs were created using monthly average estimates with 2005–2007 values; inland minus coastal difference in monthly average estimates; and yearly residential actuals from 1990 to 2009. Finally, county-level maps were created using linear regression values for electric power consumption from 1990 to 2009.

Similarly, the natural gas consumption analysis per county was divided into coastal and inland counties. Unfortunately, natural gas consumption data were not available for all counties, specifically Alpine, Del Norte, Inyo, Lake, Lassen, Mariposa, Modoc, Mono, Plumas, Sierra, Siskiyou, and Tuolumne. However, these counties represent less than 1% of the total California population from 1990 to 2009 (U.S. Census Bureau 2011). Therefore, exclusion of these natural gas consumption values should not significantly impact the analyses presented in this section. As a result, out of 46 counties with available data, 14 were considered coastal while 32 were considered inland. Graphs were created using yearly residential actuals from 1990 to 2009. Afterward, county-level maps were created using linear regression values for natural gas consumption from 1990 to 2009.

3.01.2.2.3 Results for Trends in Energy Demand for California

Electric power

Figure 13 shows plots of average monthly electric power consumption for inland counties, coastal counties, Sacramento County, and San Diego County. Such plots show the seasonal variation of energy consumption. For example, consumption for included regions increases during the summer months from May to August and generally decreases from August to April. Peak electric power consumption appears to occur in August, at which point consumption peaks at about 590 kWh per person for coastal counties and 980 kWh per person for inland counties. A possible explanation for this trend may be an increased need for space cooling, such as air-conditioning, during the summer months. Numerous studies have shown strong correlations between temperature (or heating degree days) and energy demands during summer (winter) months (Miller et al. 2008; Franco 2005; Lebassi et al. 2010; Crowley and Joutz 2005; Fung et al. 2006; Lam 1998; Le Comte and Warren 1981; Warren and LeDuc 1981; Bartholomew et al. 2002).

Interestingly, as shown in **Figure 14**, the difference between inland and coastal counties average monthly electric power consumption also appears to peak during the summer time, at 400 kWh in August. This difference in electric power consumption is consistent with recent findings previously discussed that show increasing summer temperatures in inland areas and decreasing summer temperatures in coastal areas (Lebassi et al. 2009, 2010; Sequera et al. 2011). In addition, this trend may also be affected by temperature-dependent energy demand responses within each building climate zones. For example, a recent study for California found that the energy demands of residents in some inland building climatic zones change more rapidly at higher temperatures when compared to coastal building climatic zones (Aroonruengsawat and Auffhammer 2009).

It should be noted that it appears that December electric power consumption is the highest value for both inland and coastal counties. However, it is likely that these data values result from the process by which CEC accepts electric power consumption data from energy providers, namely that adjustments can be made to previously submitted reports. These adjustments can be added to the month of December. As a result, December electric power consumption values should be disregarded.

At the yearly temporal scale, trends in energy consumption can be attributed to economic, social, and demographic factors (Lam 1998) in addition to climate responses. **Figure 15** shows yearly residential electric power consumption for the coastal

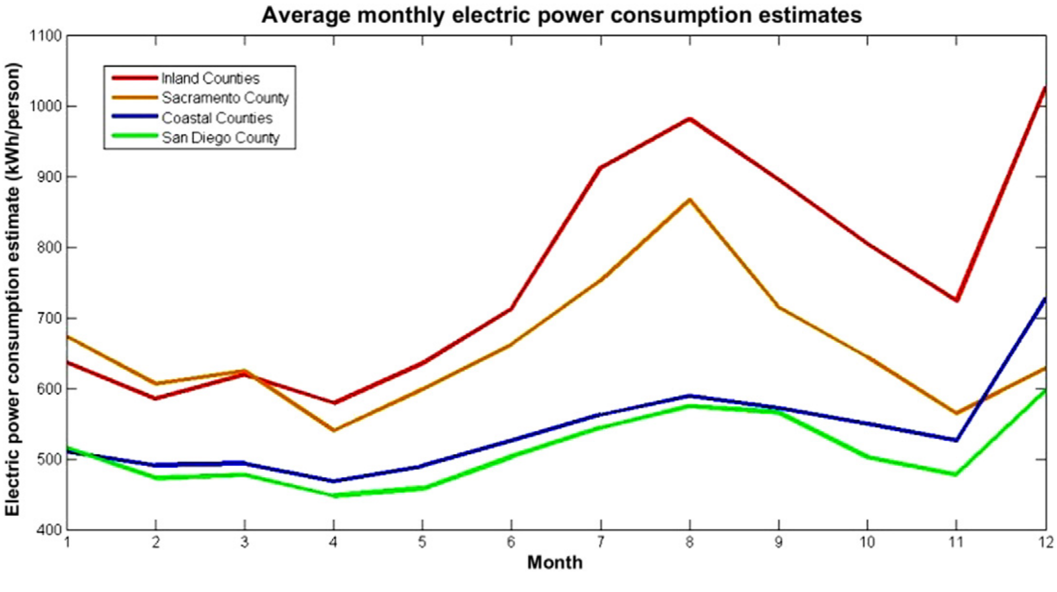

Figure 13 Average monthly electric power consumption estimates for inland counties, coastal counties, Sacramento County, and San Diego County.

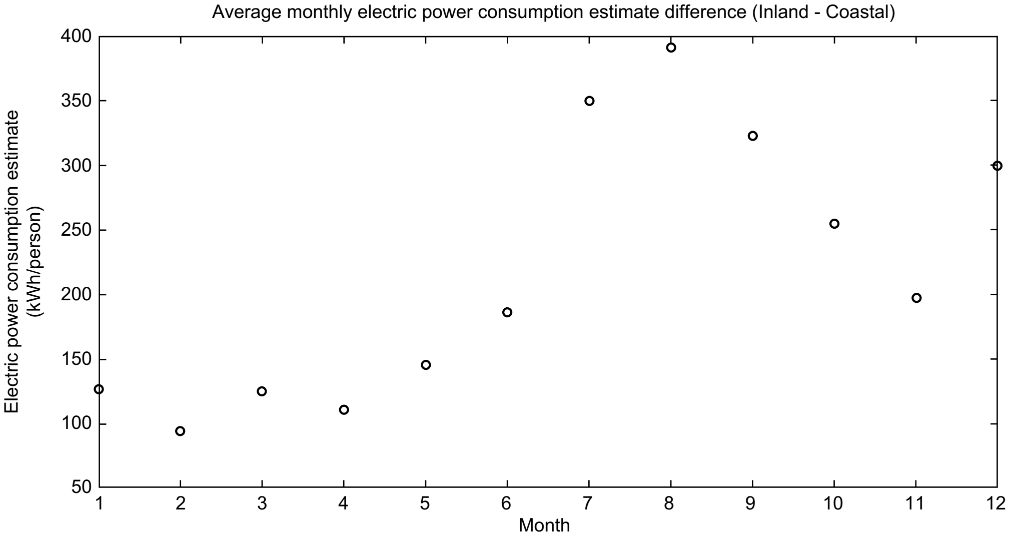

Figure 14 Average monthly electric power consumption (inland minus coastal).

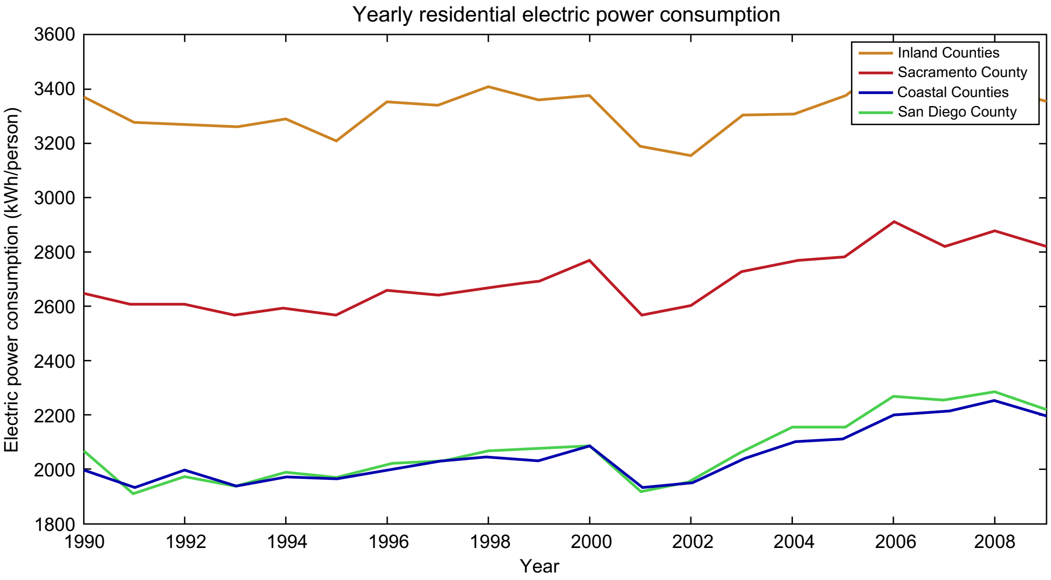

Figure 15 Yearly residential electric power consumption for inland counties, coastal counties, Sacramento County, and San Diego County.

and inland counties of San Diego and Sacramento. These areas exhibited similar increasing and decreasing patterns. Overall, electric power consumption increased from 1990 to 2009 in such areas. For example, coastal county consumption increased by 10% during this time, from about 2000 to 2200 kWh per person. Similarly, inland county consumption increased by 8%, from about 2600 to 2800 kWh per person.

In addition to the overall increasing trend from 1990 to 2009, all regions show noticeable decreases in electric power consumption in 2001. This decrease is probably attributed to increased consumer conservation and energy efficiency measures introduced in 2001 after major power outages in 2000 throughout the state (Lebassi et al. 2009). Afterward, electric power consumption appears to increase from 2001 to 2009.

Coastal county consumption is lower than inland county consumption for all years. These results are consistent with residential electric power consumption billing data obtained by the CEC (Aroonruengsawat and Auffhammer 2009). Residential billing data from 2003 to 2006 were sampled and aggregated for 16 building climate zones. As shown in Figure 16 (CEC 2011), coastal building climate zones include Zones 1, 3, 5, 6, and 7. All other zones represent inland building climate zones. The mean electric power consumption per billing cycle for coastal building climate zones was between 469 and 550 kWh per household. In contrast, the mean electric power consumption per billing cycle for inland building climate zones was between 583 and 795 kWh per household. It is possible that building climate zone, which have different

building standards, play a role in electric power consumed per household.

Figure 17 shows a map of California county-level residential electric power consumption per person per year. Counties with a positive increase in electric power consumption are shown in a range of yellow to red, with red representing the highest values. In contrast, counties with decreasing electric power consumption per person per year are shown in a range of greens, with dark green representing the highest values. It appears that, on a county-level, electric power consumption is increasing for almost all counties except three, Mono, Madera, and Stanislaus. This finding is generally consistent with the yearly analysis conducted for inland and coastal counties showing increased electric power consumption from 1990 to 2009 (Figure 15).

Natural gas

Similar to electric power consumption, natural gas consumption at the yearly temporal scale can be evaluated in the context of economic, social, demographic, and climate factors (Lam 1998). Figure 18 shows yearly residential natural gas consumption for coastal counties, inland counties, Sacramento County, and San Diego County. In general, natural gas consumption decreased from 1990 to 2009 in the included regions. In particular, coastal county consumption decreased by 22% during this time, from about 5100 to 4000 kWh per person. Similarly, inland county consumption decreased by 23%, from about 5200 KWh per person to 4000 kWh per person.

The decreasing trend in natural gas consumption is consistent with the decreasing HDD; however, other factors could be contributing including increases in natural gas prices, the

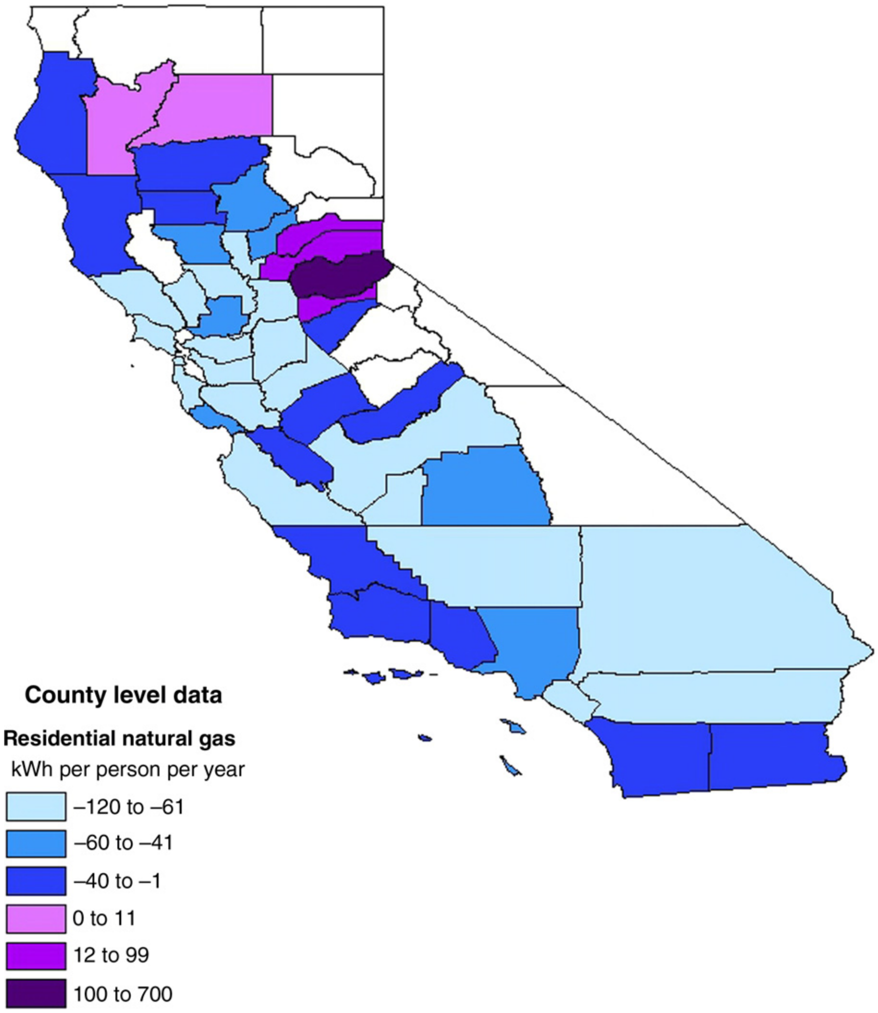

Figure 19 California 1990–2009 residential natural gas consumption per person per year.

availability of energy efficient space-heating equipment, and the use of alternative forms of energy for heating (Trends in Residential Natural Gas Consumption 2011). Moreover, the major factor influencing this trend may be the warming of temperatures during the winter time throughout California, which may lead to decreased natural gas consumption for space-heating as previously discussed (Lebassi et al. 2010).

Figure 19 shows a map of California county-level residential natural gas consumption per person per year. Counties with a positive natural consumption are shown in a range of purples, with dark purple representing the highest values. In contrast, counties with negative natural gas consumption per person per year are shown in a range of blues, with dark blue representing the highest values. It appears that on a county level, natural gas consumption is decreasing for almost all counties except six, Amador, El Dorado, Nevada, Placer, Shasta, and Trinity. This finding is generally consistent with the yearly analysis conducted for inland and coastal counties showing decreasing natural gas consumption from 1990 to 2009.

Energy analysis for the commercial and industrial sector shows less sensitivity to the climate trends of axysymmetric warming in California. Figures 20 and 21 show the aggregated electric power consumption for the industrial and commercial sector in California, excluding transportation. It can be noted that there are no significant differences between inland and coastal regions. This is clear evidence that industrial and commercial activity are driven by demands for production and consumer habits (sales), rather than responses to local weather conditions and climate trends.

Peak energy demand

Peak June, July, and August (JJA) electricity-usage trends were calculated for five California utilities for which such data were available, i.e., Sacramento Municipality Utility District, Santa Clara, Los Angeles Department of Water and Power (LDWP), Pasadena, and Riverside; the first two are in the SFBA, while the last three are in the SoCAB. Peak usage was normalized by the 1993–2004 population trends for each location. The SoCAB results (Figure 22(a)) showed coastal LDWP with the largest decrease (-0.17 kW decade^{-1} person^{-1}), consistent with its coastal marine-influenced decreased JJA CDD values of Figures 6 and 7. Midway-inland Pasadena showed only

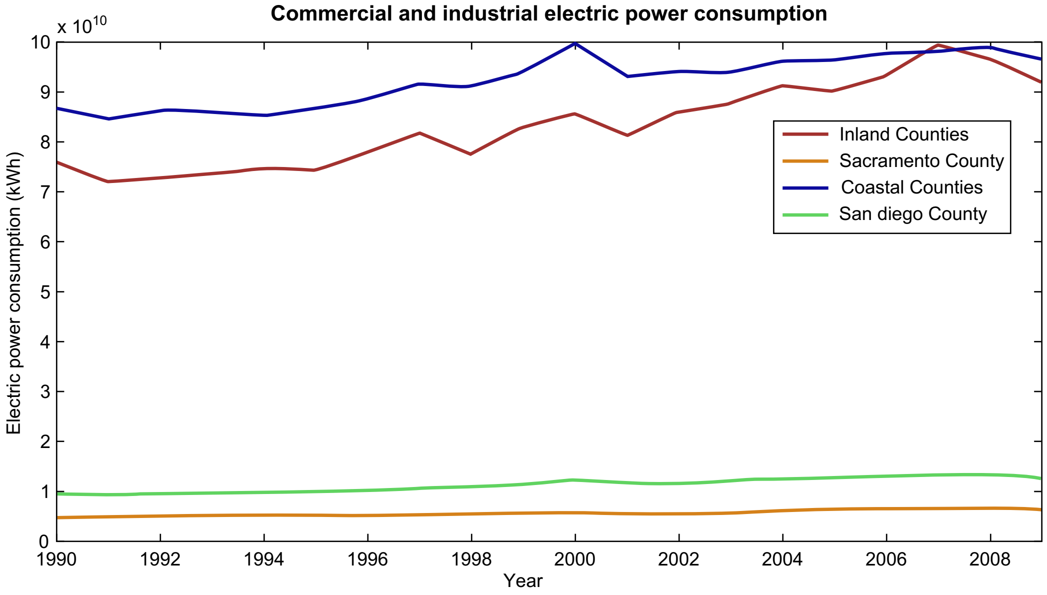

Figure 20 Yearly commercial and industrial electric power consumption for inland counties, coastal counties, Sacramento County, and San Diego County.

a small decrease (-0.01 kW decade^{-1} person^{-1}), even though its CDD trend showed a small increase. Inland Riverside had the largest increase (0.18 kW person^{-1} decade^{-1}), consistent with its inland global warming dominated increased CDDs. These peak energy-demand results are again consistent with the $T_{\max}$ results of Lebassi et al. (2009) as the peak electricity usage is associated with air conditioning usage for summer cooling. The SFBA sites of Sacramento and Santa Clara (Figure 22(b)) show increasing JJA CDD trends of 0.33 and 0.45 kW decade^{-1} person^{-1}, respectively, consistent with both their $T_{\max}$ (Lebassi et al. 2009) and CDD increases in Figures 6 and 7 but inconsistent with their inland distances. A comparable December, January, and February (DJF) analysis was not carried out, as almost all sites would show decreased HDD values and because California gas usage is minimal in summer.

California utilities for which annual natural gas data were available included Pacific Gas and Electricity, Southern California Gas Co., City of Palo Alto Gas Co., and Long Beach Gas Co. The first two are SFBA and SoCAB regional utilities, respectively, while the next two are an SFBA and a SoCAB local city utility, respectively; natural gas usage was not normalized by population trend. Annual natural gas usage for 1990 to 2007 in all four areas decreased as expected (Figure 23) due to GHG warming, with a range of values from (-5×10^6) to (-45×10^6) therms decade^{-1}. These decreasing values are consistent with the generally deceasing HDD values in Figures 8 and 9 due to GHG warming, as natural gas is mainly used for winter space heating. Although Figure 23 showed only the total utility usage, per capita values must also be downward, given the increased populations in those areas during the period of the study. The documented decreases in peak cooling and warming energy demands may also be due in some part to increased energy efficiencies.

3.01.2.2.4 Concluding Remarks on Energy Analysis for California

The analysis of California's county-level energy consumption shows similarities and differences between coastal and inland areas. First, in terms of similarities, monthly electric power consumption shows peaks during the summer time. These findings at the monthly temporal scale are suggestive of an increased need for electric power for space cooling during summer. Second, trends for inland and coastal counties peak electric power consumption show increases for inland areas and decreases for coastal areas from 1990 to 2009. Third, in terms of similarities, both inland and coastal areas show decreases in natural gas consumption. Such findings may be explained by increases in natural gas prices, the availability of energy efficient space-heating equipment, and the use of alternative forms of energy for heating. However, the correlation with climate trends is evident when compared with the surface temperature analysis (see Section 3.01.4.1 Surface Temperature Trends in California). It was shown that natural gas usage has a uniform decreasing pattern, attributed to warmer winters.

3.01.2.3 Energy Trend Forecast in California

There are many challenges to predicting electricity consumption trends since there are many factors that could play a major role in the regional consumption variability for the future. These factors could include climatic trends, electric power system details, socioeconomic trends, economic growth and technological change, demographic trends, and the effect of public policies. All these variables are very difficult to predict not only in the long range but also for a short period.

Franco and Sanstad (2008) analyzed the impact of temperature changes on summer electricity demand and peak loads using hourly electricity consumption data in the California Independent System Operator (CalISO) area. They found a very

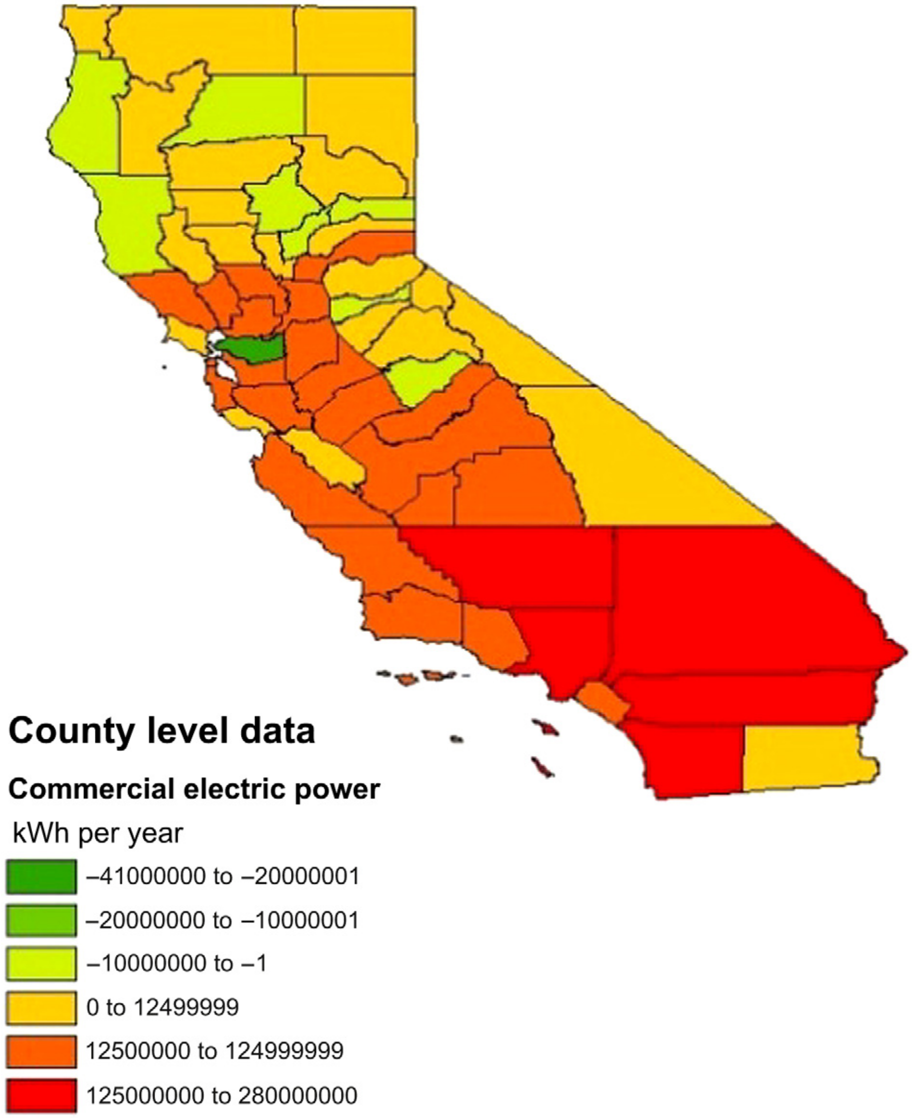

Figure 21 California 1990–2009 commercial and industrial electric power consumption per year.

high correlation ($R^2 > 0.9$) between the simple average daily temperature and daily electricity demand in the CalISO region using a cubic polynomial. The authors' interpretation of this curve was that at low temperatures, temperature increases initially result in a reduction of electric space heating and to some extent a reduction in the use of indoor appliances, the utilization of which increases during cooler weather. While at higher temperatures, the effects of space cooling via air conditioners and the uses of other appliances predominate. They also reported a high correlation ($R^2 > 0.8$) between hourly peak electricity demand in the CalISO region and the hourly maximum temperature in four locations from 2004 to 2005.

In this work, electricity consumption trends are projected into the future using the relationships derived from Franco and Sanstad (2008) as an approximation along with forecasted temperature trends from CMIP3 models (see Section 3.01.4.3), under exactly the same assumptions used by others, e.g., the underlying relationships between temperature and consumption and maximum temperature and peak demand remain invariant. Also, the equation used by Franco and Sandstad uses average daily temperature as the independent variable, so there is some bias introduced in the estimations since we used period trends for average monthly temperature. The forecast is predicted for two periods: 2011–40 and 2041–70.

As expected, annual California electricity demand shows a slight increase in all cases (Table 1) with a higher increase using the A2 scenarios (see Section 3.01.4.3). For the 2011–40 period, the A2 scenario predicts a 3.713% increase in annual electricity consumption while the B1 scenario predicts a 2.172% increase. The increase is more obvious in the 2041–70 period where the A2 scenario forecasts a 7.185% increase and the B1 scenario shows an increment of 4.683% in annual electricity consumption. Even though the projected annual electricity demand increase percentage is not very high for any of the periods or scenarios, even small percentage increases in energy demand would substantially raise energy-related expenditures (Miller et al. 2008).

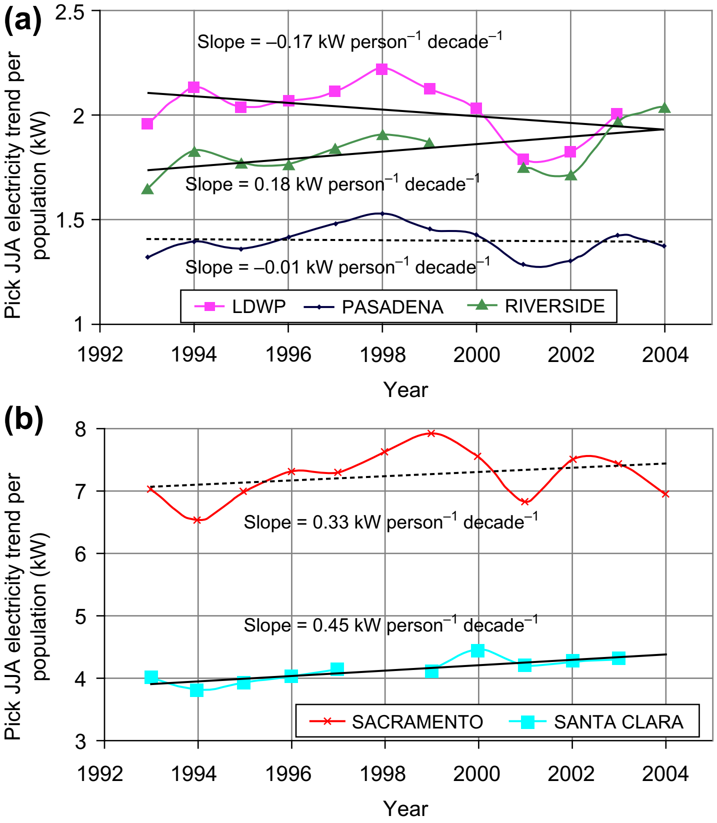

Figure 22 Trends in peak summer electricity usage at locations in (a) SoCAB and (b) SFBA (Lebassi et al. 2010).

3.01.3 Energy Demand Trends in the Northeast Corridor

This work has been extended to include connections between energy and climate for the Northeast Corridor (NEC) of the United States. An analysis of climatology, power consumption, and emissions was made for this region following the methodology used for California. This region represents approximately 4% of total power consumption in the United States. For the purpose of the energy analysis, the states that define the NEC region are Pennsylvania, New Jersey, New York, Vermont, Connecticut, Massachusetts, Delaware, New Hampshire, Maine, and the District of Columbia. State energy profiles were compiled from the U.S. Energy Information Administration (EIA) (Dzioubinski et al. 1999). Utilizing the state's energy data system from EIA, energy consumption figures were analyzed from 1960 to 2009. Residential and nonresidential sectors are presented to show the main trends within each state. In regard to the nonresidential sector, the commercial and industrial sectors are joined together to comprise the nonresidential sector. To understand the long-term energy consumption trends in the NEC, the Energy Information Administration section on State Energy System were utilized to produce a dataset that aggregated energy totals for each of the 9 states, in addition to the District of Columbia (Energy Information Administration 2011). Total sector energy data were aggregated by kilowatt hours for coal, natural gas, residential fuel, distillate fuel, kerosene, motor gasoline, and liquid petroleum gasoline. Furthermore, the data were spatially aggregated so it could be utilized to provide insights about the interaction with energy emissions and the climate.

To understand greenhouse emissions trends, historical population and urban density have to be analyzed. The United Nations Centre for Human Settlements has reported that cities account for producing the largest slice of greenhouse emissions with estimates as high as 80% for the world (Dodman 2009). It is estimated that about 43% of US. carbon emissions are produced from residential, commercial, and industrial building, and the US NEC is a highly urbanized region (Energy Information Administration 2011). According to the US Census Bureau, the Northeast is expected to expand to one-half of the US total rate by 2025 (U.S. Census Bureau 2011). The region will approximately add about six million inhabitants by 2025; this trend is a reduced one in comparison with 1995–2000. Further, the Northeast region contains five major urban centers: Boston, New York, Philadelphia, Baltimore, and Washington DC.

According to the Northeast Data Abstract of EIA in 1997, the Northeast has an estimated 20 million households compared to the total 102 million of the United States. Household energy consumption represents about 2.4 quadrillion BTU out of the 10 quadrillion consumed by the United States. This represents one of highest household energy consumption in the world (Dzioubinski et al. 1999).

For the NEC, the residential sector shows a dramatic decrease in energy consumption. In Figure 24, for 1960, the

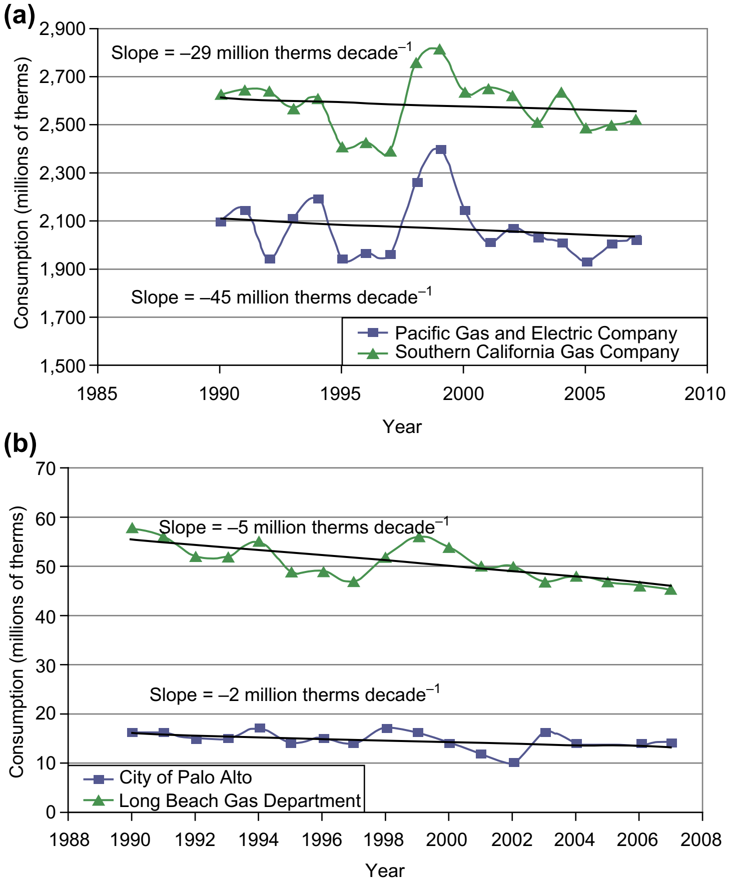

Figure 23 Trends in peak winter gas usage at selected locations (Lebassi et al. 2010).

data indicate that per capita the residential sector of the Northeast region annually consumed 14 000 kWh per person, reflecting a peak by the mid-1970s. By the year 2009, the number had substantially decreased down to 10 000 kWh per person or a 37% change. The substantial decrease over a period of four decades can be attributed mostly to increased energy efficiencies in buildings, and may be due to a warming climate reflected mostly in warmer winters.

Data also suggest that nonresidential energy consumption rapidly rose since 1960 with a maximum in the 1970s (see Figure 25). The years proceeding depict a sharp decline in nonresidential energy consumption. A number of factors have contributed to the decline such as urbanization, which determines fuel type usage, energy efficiency, and stronger environmental legislations that were enacted, such as the National Environmental Policy Act in 1970. Figure 25 clearly shows that over a period of time there has been a change in nonresidential fuel usage. In 1960, coal usage composed a significant slice of energy consumption. After 1981, a substantial decrease occurred while natural gas energy consumption rose during that same period of time. Natural gas is a cleaner burning fossil fuel than coal. Coal is one of the primary contributors of greenhouse emissions.

Table 1 Estimated changes in annual California electricity demands for different scenarios

Period	*Scenario*	*Increase in annual electricity consumption (%)*
2011–40	A2	3.713
2011–40	B1	2.172
2041–70	A2	7.185
2041–70	B1	4.683

At the sector level, CO_2 emissions associated to residential energy demand drastically decreased over 37% per capita, attributed to energy efficiencies and possibly to a warmer region in the winter. Despite these trends, the NEC region continues to be one of the largest CO_2 sources of the United States accounting for more than 15% of all emissions with an increasing trend. These results demonstrate the vulnerability of the region to climate changes and possible ways to mitigate impacts.

The residential sector represents a large portion of the regional energy budget, and it may be the most vulnerable of all sectors to a warming climate, particularly in summer. Expected mean increases may be mitigated by better energy technologies, as was shown in this analysis. This may differ for extreme summer events, such as heat waves, as was the case of California.

The data for the NEC also suggest that more warming is occurring along coastal areas versus inland temperatures (see

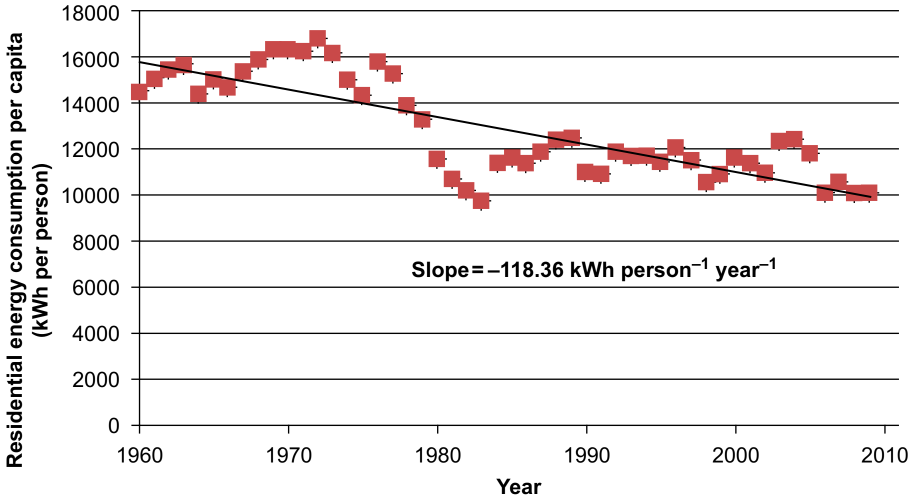

Figure 24 Total Northeast residential energy consumption per capita, 1960–2009.

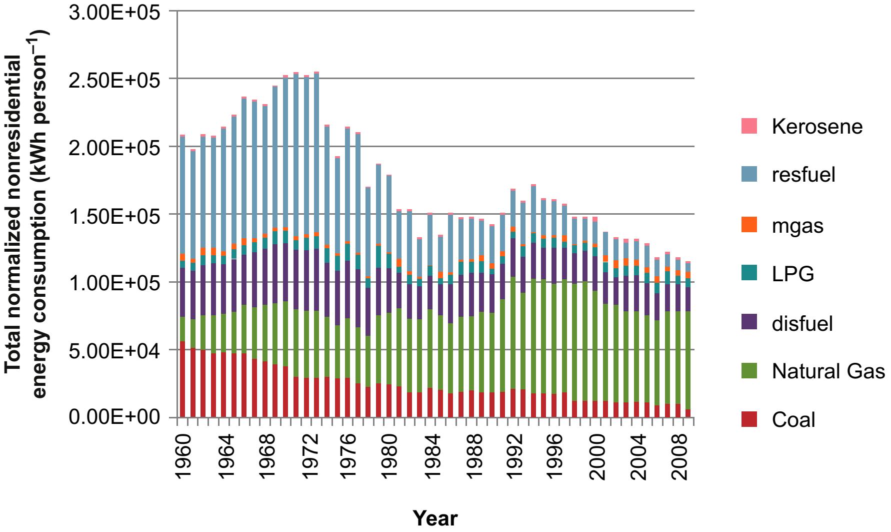

Figure 25 Total Northeast nonresidential energy consumption by fuel type per capita, 1960–2009.

Section 3.01.4.4 Climate Trends in the US Northeast Corridor). Several variables could contribute to the difference in warming. Most major cities lie along coastal areas, Boston, New York, Baltimore, and Washington D.C., contributing to higher levels of anthropogenic emissions and increased occurrence of the UHI effect. A second key variable is a warmer global climate that is reflected mostly in warmer Sea Surface Temperatures (SSTs). However, the total or relative contributions of these two variables (land use for urbanization and SSTs due to global warming) are not known for the NEC.

It can also be inferred that minimum temperatures are the key controlling variables in energy demands for this region, due mostly to the cooling trend. This is reflected in the larger decrease in natural gas (winter) over electricity (summer). The overall effect seems to indicate that under mean conditions, the energy sector may be less vulnerable to climate changes in these Northern regions.

3.01.4 Temperature Trends Analysis

3.01.4.1 Surface Temperature Trends in California

To better understand the temporal and spatial energy trends presented in the previous section, it is necessary to discuss the climatic trends. Many studies have confirmed that average California 2-m temperatures increased over the past decades. In particular, during the summer, these trends show diurnal asymmetric warming rates, where nighttime minimum temperatures ($T_{\min}$) have warmed faster than daytime maximum values ($T_{\max}$), thus decreasing the daily temperature range. The observed asymmetric warming during the last three decades at California coastal sites have been attributed to increases in cloud cover (Nemani et al. 2001), Sea Surface Temperatures (Goodridge 1991; Karl et al. 1993), upwelling (Bakun 1990; Snyder and et al. 2003; McGregor et al. 2007), land use changes for urbanization (Pielke et al. 2002; Chase

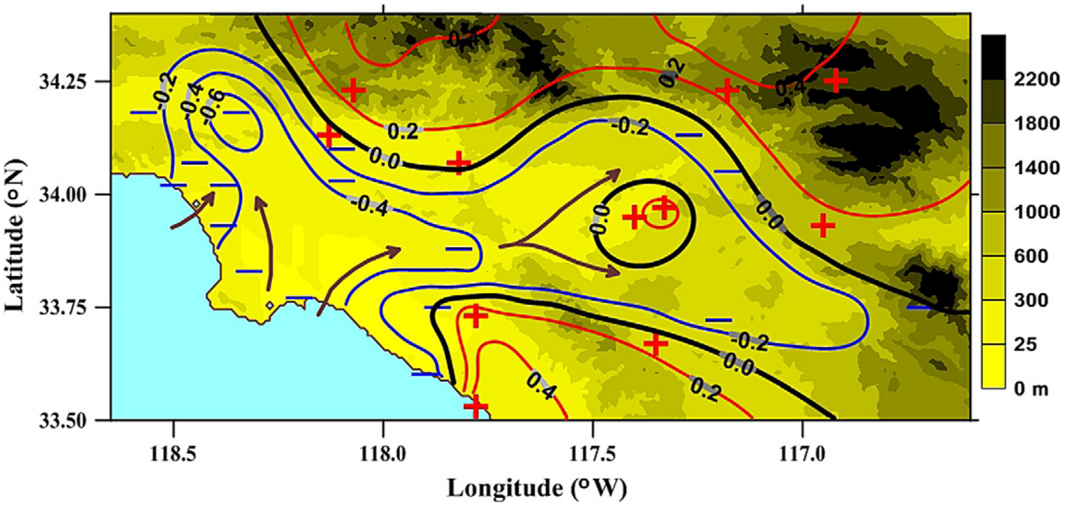

Figure 26 SoCAB 2-m summertime maximum-temperature trends (°C decade^{-1}); arrows indicate predominant summertime flow-patterns, pluses/minuses (+,−) warming/cooling stations, blue/red isotherms cooling/warming areas, red dashed line (extrapolated warming rate), and black isotherms zero-change lines (Lebassi et al., 2009).

et al. 2000; Mintz, 1984; Zhang et al. 1997), irrigation (Christy et al. 2006; Kueppers et al. 2007; Bonfils and Lobell 2007), Greenhouse Gas (Duffy et al. 2007; Walters et al. 2007; Cayan et al. 2008), and/or Urban Heat Islands (LaDochy et al. 2007).

Most recently, Lebassi et al. (2009) evaluated 1970–2005 summer JJA mean monthly maximum air temperatures for two California air basins, SFBA and SoCAB, using data from 253 California COOP weather sites and looking at daily minimum (T_{min}) and maximum (T_{max}) temperatures in order to obtain average monthly values (T_{ave}). They found that when values for all stations were combined, that period showed a general increase of 0.23 °C decade^{-1}. As previously stated by other authors, this warming trend is asymmetric since T_{min} values (0.27 °C decade^{-1}) increased faster than T_{max} values (0.04 °C decade^{-1}). These results are consistent with the previously observed asymmetric global warming (due to increased greenhouse gases). However, the most important aspect of that work is the fact that the T_{max} values in both air basins exhibited a complex pattern with cooling in the low-elevation coastal areas open to marine air penetration and warming at both inland and higher elevation coastal areas (Figures 26 and 27).

In SoCAB subareas, the statistical significance of T_{max} trends show unexpectedly larger trends and higher significance levels for a coastal cooling area (−0.33 °C decade^{-1} and 87%, respectively) than for an inland-warming area (0.21 °C decade^{-1} and 74%, respectively). On the other hand, statistical significance levels in the cooling and warming regions in the SFBA show stronger trends and higher significance values for the inland-warming areas (0.47 °C decade^{-1} and 95%, respectively) than the coastal cooling areas (−0.16 °C decade^{-1} and 72%, respectively), reversed from the SoCAB results because of the more complex SFBA topography (Lebassi et al. 2009). Both inland areas have a combined warming rate of 0.40 °C decade^{-1} and a 93% significance level, while the weaker combined coastal cooling rate (−0.22 °C decade^{-1}) was significant only at the 83% level. The authors hypothesized that this cooling effect was the consequence (and may be a 'reverse reaction') of global warming in inland areas, which resulted in increased sea breeze flow activity. This hypothesis is supported by General Circulation Models T_{ave} output, which showed warming that decreased from 0.13 °C decade^{-1} at inland sites to 0.08 °C decade^{-1} in coastal areas for the same time period and also sea-level pressure increases in the Pacific High and decreases in the inland thermal low. Moreover, pressure gradients showed a trend of 0.04 hPa, 100 km^{-1} decade^{-1}.

However, this coastal cooling effect takes place in the rest of the California coast and is not only reserved for the two air basins. Figure 28 shows the distribution of the maximum monthly T_{max} trends for the summer across the state of California. Similar patterns to the ones seen in the two air basins are shown within the entire state, that is, cooling trends at low-elevation coastal sites and warming trends at both inland and high-elevation sites. More extensive statistical analyses of the distribution of these trends show that the majority of the cooling sites are located at elevations lower than 100 m above sea level as well as distances from the coast less than 70 km, which suggests that 100 m and 70 km are good threshold values to classify a location as a low or a high-elevation site as well as a coastal or an inland site. Also, these values determine the extent of the sea-breeze intrusion and thus the spatial extent of this coastal cooling effect.

3.01.4.2 California Surface Air Temperature Extremes and Heat Waves

Impacts of climate on energy may also be reflected on peak demands, which result from extreme events, such as heat waves. In previous sections, the trends on peak energy demands were discussed for California (Figures 22 and 23). Summer energy peaks may be the result of heat waves. Heat waves may increase in frequency, severity, duration, or areal

Likelihood of Heat Disorders with Prolonged Exposure or Strenuous Activity

🟨 Caution 🟨 Extreme Caution 🟧 Danger 🟥 Extreme Danger

Figure 29 Heat index (H_i) (°F) = f(T, RH); from NOAA website, where a T of 95 °F (35 °C) and RH of 50% yields a H_i of 105 °F (Robinson, 2000).

extent due to the effect of global warming. Heat waves may also decrease due to the 'reverse reaction' discussed in the previous section. The U.S. National Weather Service (NWS) declares heat watches and warnings when the heat index is greater than or equal to 105 °F (40.56 °C) during the daytime and greater than or equal to 80 °F (26.66 °C) at nighttime for at least two consecutive days or for a period of at least 48 consecutive hours. Robinson (2000) proposed that extended heat waves exist, if the period is 96 consecutive hours or greater. The heat index (H_i) is a combination of ambient temperature and humidity that approximates the environmental aspect of the thermal state regime of the human body, with NWS thresholds representing a generalized estimate of the onset of physiological stress.

Daily maximum temperatures (T_{max}) for 28 Cooperative network sites in SoCAB from 1970 to 1974 and 2006 to 2010 were analyzed to investigate frequency and intensity of heat waves in California. The NCDC web climate record documented that average summer SoCAB afternoon relative humidity (RH) is about 50–60%. The National Oceanic and Atmospheric Administration (NOAA) gives a heat index value of 105 °F (40.56 °C) for a temperature of 95 °F (35 °C) and RH value of 50%, shown in Figure 29. As we do not have nighttime temperature values, our heat wave and extended heat wave criteria thus only involve daytime T_{max} values greater than or equal to 95 °F (35 °C) for two and four consecutive days, respectively.

As many climate impacts depend on extreme T_{max} values and not just average monthly T_{max} values, Figure 30 shows the SoCAB distribution of the highest T_{max} values anytime during the period from 1970 to 2010. Three subareas are visible with a boundary temperature of 34 °C (and with the following ranges): (a) cool coastal (27–34 °C), (b) cool mountaintops (28–34 °C), and (c) in-between hot area (34–40 °C). Trends in these extreme T_{max} values are shown in Figure 30: (a) decreases up to −0.8°C per decade in the coastal cooling areas, (b) increases up to 0.6°C per decade in the inland and mountain warming areas, and (c) increases up to 0.4 °C per decade in the high-elevation coastal warming areas. Note that these trends are even larger than those in the monthly averaged T_{max} values in Lebassi et al. (2009). Also note the extension of coastal cooling into the mountain pass on the northern SoCAB edge and into the eastern valleys of the basin.

The analysis of spatial distribution of 1970–74 and 2006–10 in days year^{-1} (Figures 31 and 32, respectively), with daily T_{max} greater than or equal to (a) 85 °F (29.44 °C), (b) 90 °F (32.22 °C), and (c) 95 °F (35 °C), resulted in coastal and mountain areas having fewer hot days and inland areas having more hot days. Isopleths increment and boundary value (but not boundary location) change from graph to graph. The difference between 2006–10 and 1970–74 in days year^{-1} (Figure 33), with daily T_{max} greater or equal (a) 85 °F (29.44 °C), (b) 90 °F (32.22 °C), and (c) 95 °F (35 °C), resulted coastal low-elevation areas having large decreases, of up to −32, −24, and −16 days year^{-1}, for 85 (29.44 °C) to 95 °F (35 °C), respectively. Mountain areas have large increases, of up to 28, 20, and 12 days year^{-1}, for 85 (29.44 °C) to 95 °F (35 °C), respectively. Inland low-elevated areas and elevated coastal areas have smaller increases, of up to 18, 8, and 4 days year^{-1}, for 85 (29.44 °C) to 95 °F (35 °C), respectively. Maximum decreases in hot days were not located at the coast, as the coastal effect was always there.

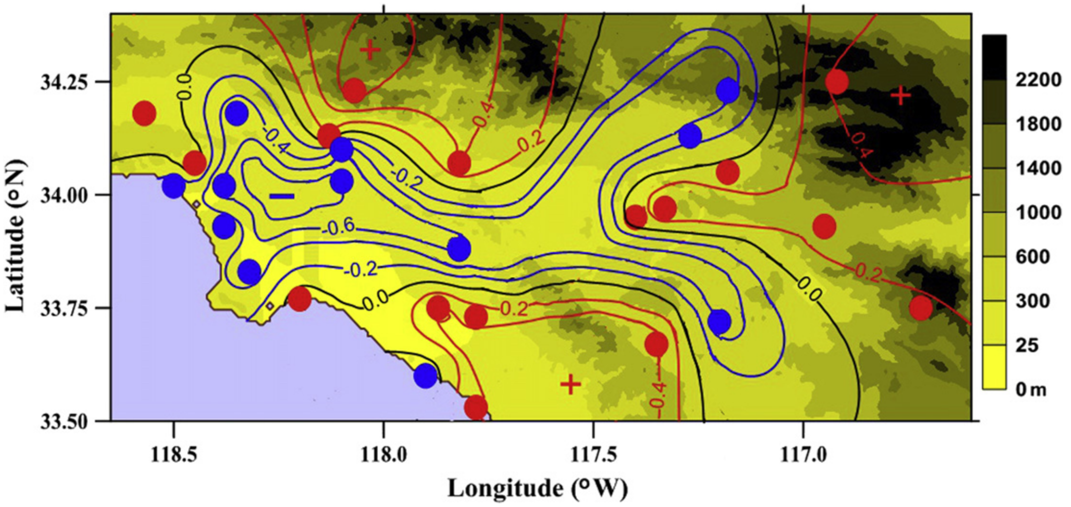

Figure 30 Extreme (highest) T_{max} (°C) value anytime from 1970 to 2010 (upper) and their trends (°C decade^{-1}) over that period (lower).

The analysis of spatial distribution of exactly 2-day heat waves and 4-day heat waves in days year^{-1} (**Figures 34 and 35**), with T_{max} greater than or equal to 95 °F in (a) 1970–74, and (b) 2006–10 resulted in a maximum number of heat waves in inland areas, few in coastal areas, and none in mountain areas. The analysis of changes (**Figures 34 and 35**) (c) 2006–10 values minus 1970–74 values period indicates the following. For coastal low-elevation areas there are large decreases, of up to −11 days 5 years. For mountain areas there is no significant change. For inland low-elevation areas and elevated coastal areas there are smaller increases, of up to 4 days 5 years.

3.01.4.3 Temperature Forecasts in California

The relationship between climate and energy for California was discussed in great detail in previous sections of this chapter. In this section, the surface temperature trends are forecasted for the future by using downscaled outputs from a series of Global Circulation Models (GCMs) under different projected climatic scenarios for the twenty-first century. The focus in this section is centered on the variation of surface.

Outputs from monthly average temperature simulations from two scenarios (A2 and B1) for future greenhouse gas emissions forcing global climate are used to estimate electricity demands for the summer in the twenty-first century in California. It should be noted that these scenarios are defined in the Intergovernmental Panel on Climate Change Special Report on Emissions Scenarios (SRES) (IPCC 2000) and each one is simulated by 16 CMIP3 models. CMIP3 stands for the World Climate Research Programme's (WCRP's) Coupled Model Intercomparison Project, Phase 3: Multi-Model Dataset (CMIP2 models). CMIP3 models include BCCR-BCM2.0, CGCM3.1, CNRM-CM3, CSIRO-Mk3.0, GFDL-CM2.0, GFDL-CM2.1, GISS-ER, INM-CM3.0, IPSL-CM4, MIROC3.2, ECHO-G, ECHAM5, MRI-CGCM2.3.2, CCSM3, PCM and UKMO-HadCM3.

The models used in this work were taken from the "Bias Corrected and Downscaled WCRP CMIP3 Climate Projections" archive at http://gdodcp.ucllml.org/downscaled_cmip3_projections. This archive contains 112 projections of monthly temperature and precipitation at 1/8 degree resolution over the contiguous United States, developed using the "Bias-Correction Spatial Disaggregation" (BCSD) downscaling technique (Maurer et al. 2007).

Trends for summer average temperature for three periods (1950–2010, 2011–40, and 2041–70) were obtained by using the median for average JJA temperatures of the 16 models for each of the two scenarios. The SRES A2 (~'higher' emissions path) considers slower technological change and economic growth and higher population growth, while the SRES B1 (~'lower' emissions path) considers rapid change in economic structures toward service and information, with emphasis on clean sustainable technology, as well as reduced material intensity and improved social equity.

The first period (1950–2010) corresponds approximately to the same period presented in the previous section. This period (**Figure 36**) shows similar patterns with lower trends toward the coast (0.10–0.12 °C decade^{-1}) and higher temperature increases for the same period at inland regions (up to 0.3 °C decade^{-1}). It is important to note that these trends are consistent with the observational analyses performed by Lebassi et al. (2009). However, the models are unable to capture the coastal cooling features. This is probably due to the fact that these models were statistically downscaled from the original runs with 2° resolution grids and the coastal cooling phenomena occur at smaller scales (approximately 0.5°).

The second period (2011–40) shows similar spatial patterns than the previous period but the trend values are different in both scenarios, and also, the values increase with respect to the previous period. The A2 scenario (**Figure 37**) presents values that range from 0.19 °C decade^{-1} at the coast to 0.45 °C decade^{-1} further inland while the B1 scenario (**Figure 38**) has similar values to the 1950–2010 period (0.1–0.27 °C decade^{-1}). Finally, the third period (2041–70), as expected, reflects highly increasing trends all over the region for both scenarios, being the A2 scenario

Figure 33 Spatial distribution of difference between 2006–10 and 1970–74, days year^{-1}, with daily T_{max} greater or equal to (a) 85 °F (29.44 °C), (b) 90 °F (32.22 °C), and (c) 95 °F (35 °C).

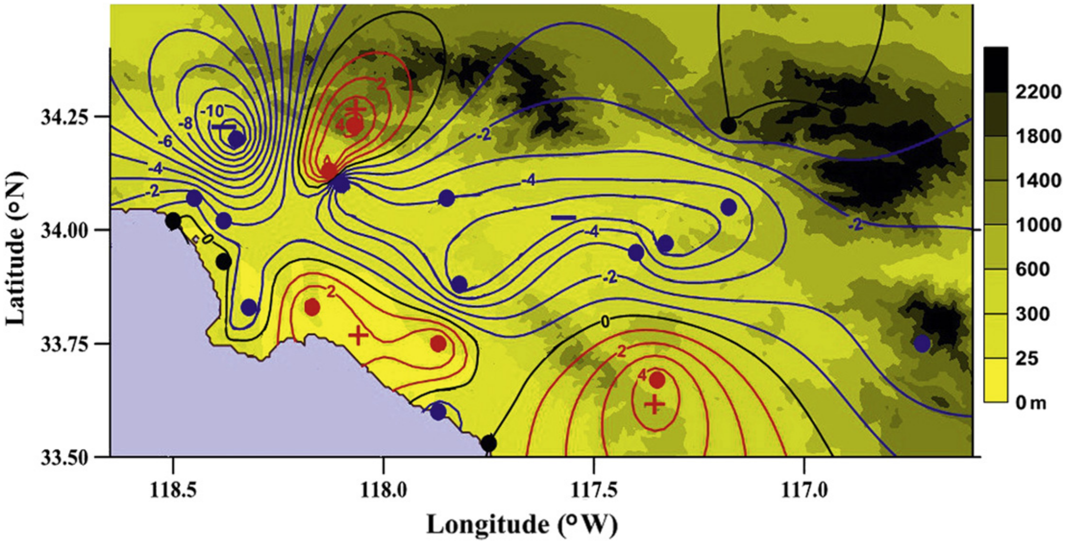

Figure 34 Spatial distribution of exactly 2-day heat-waves (days per 5-years) with $T_{\max}$ greater or equal 95 °F (35 °C) in (a) 1970–74, and (b) 2006–10, and (c) 2006–10 values minus 1970–74 values.

(0.2–0.74 °C decade^{-1}) (Figure 39) overall higher than the B1 scenario (0.16–0.64 °C decade^{-1}) (Figure 40). It is also important to note that the spatial pattern for the A2 scenario changes as the temperature increases with latitude instead of distance from the coast.

3.01.4.4 Climate Trends in the US Northeast Corridor

An accumulation of scientific evidence over the past decade reveals that climate change impacts are already being experienced in the NEC (Hayhoe et al. 2007). Previous sections of this chapter explored the long-term trends of energy demands in California and the NEC. This section details the trends in climate as reflected in changes surface temperatures and precipitation on the NEC for the past 30 years (1980-2010).

Surface temperature and precipitation datasets were used to produce this analysis. Monthly records from NWS COOP stations were used in the analysis. Precipitation and temperature data from 372 stations over the 9 states in the Northeast region were used for a period of time comprising from 1980 to 2010. Mean maximum and minimum surface temperature as well as precipitation profiles were generated by examining inland and coastal areas. The criteria to select the stations were based on the diversity of the regions to capture axisymmetric warming trends (Karl et al. 1988). The three variables utilized to generate the dataset were maximum mean surface temperature ($T_{\max}$), minimum mean surface temperature ($T_{\min}$), and mean precipitation. The data consisted of daily $T_{\min}$ and $T_{\max}$ temperatures. Daily average temperatures were used to produce average monthly $T_{\max}$ and $T_{\min}$ temperatures. Months with more than 5 days of missing data and/or sites with less than 15 years of data were not used in the analysis. This effort produced a comprehensive climatology dataset for the Northeast region.

Two phenomena were observed in the NEC region that clearly show warming and cooling regions. The NCDC COOP stations $T_{\max}$ data show that the whole NEC coast is warming in the period of time that comprised the last 30 years (Figure 41). A total $T_{\max}$ and $T_{\min}$ variability of 0.011 and 0.061 °C decade^{-1}, respectively, were observed during this period of time. Also, in Figure 41 it can be observed that the $T_{\min}$ trend warmed faster than the $T_{\max}$ trend. Some studies suggest that a slow variation in $T_{\max}$ could be due to irrigation and other agricultural land-use practices (Chase et al. 2000; Betts 2001), but an acceleration in a warming $T_{\min}$ trend may also be the result of deforestation (Pielke et al. 2002; Defries et al. 2002). An examination of the spatial trends in the NEC region (Figures 42 and 43) shows that while the $T_{\max}$ warming trend is slower, most of the stations in the NEC had an increasing trend. Most notably is the 2 °C decade^{-1} increase in the Portland, Maine COOP station. Certain inland areas are showing the opposite trend. For example, these regions, such as the rural area of Chemung, New York, show cooling during the summer time. However, inland areas that are densely populated, such as the Pittsburgh metro region, show warming trends that can be attributed to UHI effects. Most major metro regions are located in coastal regions and show warming patterns for both $T_{\max}$ and $T_{\min}$, which could be attributed to a combined effect of global warming and UHI. The summer maximum for inland areas reflects an increase of 0.2 °C decade^{-1} (see Figure 42). In contrast, the summer maximum for coastal areas shows warming sites increasing at a rate of 0.4 °C decade^{-1} (as shown in Figure 42). Winter climate reflects all warming $T_{\min}$ sites across the region with a maximum of 2 °C decade^{-1} (Figure 43). In summary, observations show that the NEC coast is warming during the summer and during the winter at a faster rate. These results contrast with the California case, as previously discussed, during the summer but entirely agree for the winter.

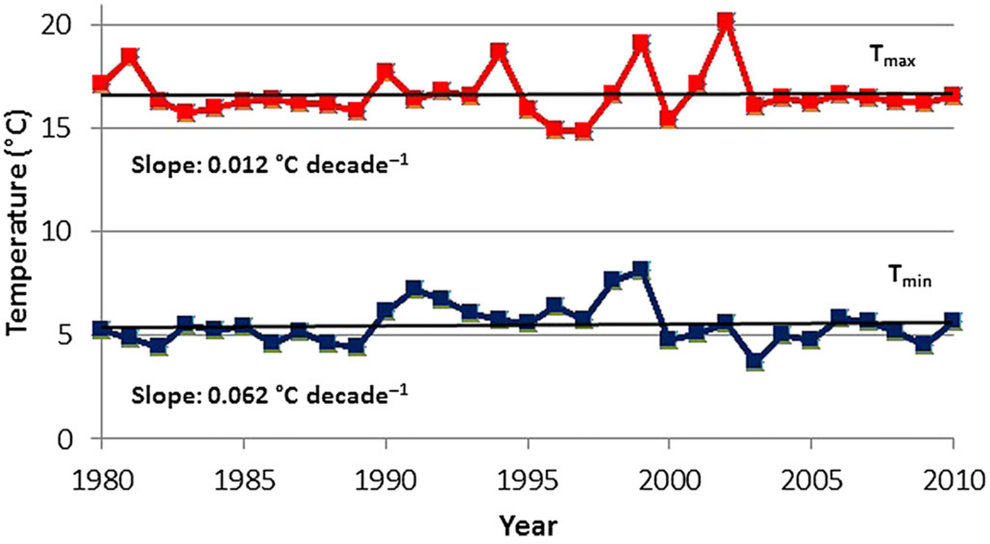

Figure 41 Total variation of T_{max} and T_{min} (1980–2010) for the U.S. North East Region.

The climate trend analysis also shows a uniform increase in precipitation within the region. Figure 44 shows that the entire NEC region has an increasing precipitation trend with inland sites presenting an increase of mean precipitation in the order of 0.2 mm decade^{-1}, while coastal sites in the entire NEC had an average positive change of 0.21 mm decade^{-1}. While the focus of this chapter is on end-user demands, precipitation findings suggest that water supplies may not risk energy production by hydro-sources for the NEC.

3.01.5 Summary

This chapter reviewed the relationship between energy and climate trends within the context of populated coastal regions. Energy activity is sensitive to climate in several ways: demand from end users is directly influenced by long climate variability for space heating and cooling of buildings and homes, extreme climate events drive the peak demand grid exposing the vulnerability of the energy production infrastructure, and changes in water supply may impact energy production from hydro-plants. A warming climate in Northern latitudes may, therefore, drive increasing demands in summer time and reduce demands in winter seasons. This chapter looked at the question from the end-user perspective by analyzing climate trends in two distinct coastal regions in the United States; Coastal California and the Northeast Corridor, both similar in population but different in climate. In response to climate patterns, a correlation was found between surface temperature trends and energy demands for the residential sector and little sensitivity in the commercial and industrial sectors. The case of coastal California suggests a decrease in summer peak energy demands consistent with cooling temperature trends, which contrasts with climates warming around the world. This suggests that regions should be carefully looked at to account for local factors such as topography. In general, it can be inferred that Northern latitude energy infrastructures may be less vulnerable to climate trends than anticipated.

Methods used in this chapter may be employed to analyze the nexus between energy and climate in other locations of the world. Future works should also look at the nexus between climate and renewable energy resources such as wind, solar, and hydro power.

Acknowledgments

This work was made possible in part by the following supporting agencies:

- U.S. National Oceanic and Atmospheric Administration, Office of Education Educational Partnership Program award NA11SEC4810004.
- U.S. National Science Foundation under Grant Nos. AGS-1062934 and 0933414.
- U.S. Department of Education under Grant No. P031M105066.

The statements contained within this chapter are not the opinions of the funding agencies or the U government, but reflect the author's opinions.

We would especially like to thank Mr. Steven Mac and Ms. Andrea Gough at the California Energy Commission. We also acknowledge the cooperation of the modeling groups; the Program for Climate Model Diagnosis and Intercomparison (PCMDI) and the WCRP's Working Group on Coupled Modeling (WGCM) for their roles in making the WCRP CMIP3 multi-model dataset available. Support of this dataset is provided by the Office of Science, U.S. Department of Energy.

3.02.1 Introduction

3.02.1.1 Growing Global Demand for Energy

Buckminster Fuller is quoted as saying, 'Real wealth is ideas plus energy.' Despite the fact that his statement was not intended to describe the relationship between economic growth and energy use, the quote still succinctly describes the importance of energy in our economy. The global population is growing both in number and in its per capita use of energy as increasing fractions of the world's population come out of poverty. Energy growth is thus growing more quickly than the population. Over 80% of today's energy comes from fossil

http://dx.doi.org/10.1016/B978-0-12-384703-4.00304-X

fuels, which are the major anthropogenic source of carbon dioxide (CO_2). CO_2 is one of the first order human climate forcing agents and is of concern because it is the largest human-emitted radiative forcer and has a long (decades to century) atmospheric lifetime (National Research Council 2005, 2010a). The challenge faced by the world is to maintain economic growth, driven by energy, while at the same time reducing carbon emissions. In this chapter, the term 'carbon' refers primarily to CO_2 and methane (CH_4). 'Carbon' is sometimes used as shorthand notation to include radiative forcing agents more generally, including aerosols, which (depending upon composition and location) can result in either increases or decreases in radiative forcing.

The term 'energy' is used here as shorthand for the complex technological systems that extract, refine, transport, and apply the world's energy resources to meet our fundamental demands for food, clean water, transport, space conditioning, and other end uses. The development of such complex technological systems has been likened to the evolution of ecosystems (Arthur 2009). As with biological ecosystems, technological systems evolve to succeed within a range of experienced external conditions. The most successful systems, whether biological or technological, are able to adapt as the range of external conditions change. However, the success of these systems becomes vulnerable when conditions change more rapidly than the ability of the system to respond. Vulnerability is therefore most strongly related to the amplitude and rate of change beyond the historical range of conditions within which a system evolved.

Environmental, industrial, and societal systems – including systems that produce, deliver, and convert energy – that have evolved within historical climate patterns would be impacted in the event of significant decadal-scale changes in temperature, precipitation, and other weather event characteristics. The term 'climate' is used in this chapter as the average temperature and precipitation over a multidecadal period, and includes measures of the type, frequency, and intensity of weather events, and a change in climate likewise refers to a change in the averages of these parameters over a multidecadal period (The 30-year period from 1970 to 2000 is often used as the statistical basis for comparison). There is a potential for these changes to become more pronounced in future years, particularly toward the end of the twenty-first century (Meehl et al. 2007; National Research Council 2010b). Because climate is a long-term phenomenon, and because historical experience indicates that significant changes to the energy system take decades to occur (Kramer and Haigh 2009; Smil 2010), it is appropriate to think about the vulnerabilities of fossil fuel energy resources to climate over a period of several decades. A time frame of about 40 years seems to be appropriate, for several reasons.

The combustion turbine, natural gas-combined cycle power plants, and natural gas liquefaction were in their early stages of development 40 years ago (approximately 1970), and have since helped to drive the global fraction of natural gas consumption from 18 to 24% (see Figure 1), while petroleum consumption dropped from 45 to 35% (although it is still the largest primary energy source). Coal consumption has remained about constant as a fraction of total energy (31% of world primary energy in 1970 and 29% in 2009) (BP 2010).

The year 1970 also marks a point at which consideration of the environment began to play a much greater role in how energy is produced and used, with the founding of the US Environmental Protection Agency as a major indicator of these growing environmental concerns. In the United States, the Clean Air Act was passed in 1970, marking a major advance in the control of air pollutant emissions, largely from energy production systems.

The world's economy had grown by a factor of about 20 since 1970 (World Bank 2011), while world population has almost doubled, from 3.7 billion people in 1970 to 7 billion today (United Nations 2011). Energy consumption has increased slightly faster than population, from 56.5 to 69.2 kJ per person (BP 2010), and CO_2 emissions per person have increased by about 10% over the past 40 years (Boden et al. 2011). Even so, energy use per dollar of GDP and CO_2 emissions per dollar have both dropped by roughly a factor of 10 over the same period.

It is clear that there have been major technical, social, and economic changes over the past 40 years, and these have substantially influenced and have been influenced by the world's energy system (Wilbanks et al. 2008). The importance of energy to economic growth and social well-being is well documented. The question is how global environmental effects, including climate, will influence and be influenced by energy production and use over the *next* 40 years.

A 2009 study, based on a reduced complexity coupled carbon cycle–climate model, estimated that no more than 1000 Gt of CO_2 can be emitted between 2000 and 2050 to have a reasonable probability (more than 25%) of maintaining average global surface air temperature rise to less than 2 °C (Meinshausen et al. 2009). This conclusion is based upon the sensitivity of temperature to atmospheric greenhouse gas (GHG) concentrations as reported in the 2007 Assessment Report from the Intergovernmental Panel on Climate Change (IPCC) (Solomon et al. 2007). To meet this IPCC target, it is likely that per capita CO_2 emissions would need to be roughly 10% of what they are today.

Meeting such levels of CO_2 reductions is a daunting task given the current connections between population growth, economic development, energy use, and CO_2 emissions. A straightforward relationship between these factors is described by the Kaya identity (Yamaji et al. 1991),

$$\mathrm{CO_2} = \text{Population} \times \left(\frac{\text{GDP}}{\text{person}}\right) \times \left(\frac{\text{energy consumption}}{\text{GDP}}\right) \times \left(\frac{\mathrm{CO_2}}{\text{energy consumption}}\right)$$

where GDP is the gross domestic product. From this broad perspective, CO_2 emissions can be reduced by reducing population, per capita GDP, energy per dollar of GDP, or CO_2 per unit energy consumption. From a technological perspective, energy efficiency (energy per dollar of GDP) and low carbon energy (CO_2 per unit energy consumption) are the most common targets for reducing CO_2 emissions. Economic efficiency efforts have resulted in enormous improvements in energy consumption per dollar of GDP and in emissions of CO_2 per dollar of GDP – the product of the last two terms in the Kaya identity. However, the rate of technological

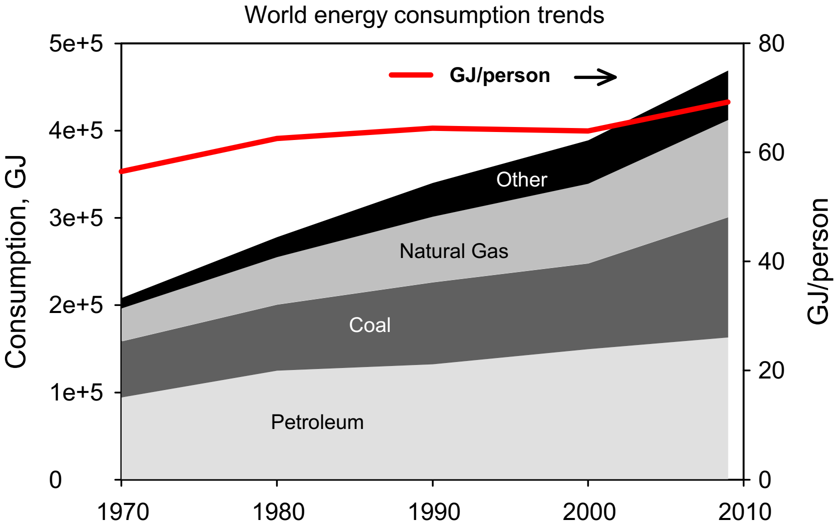

Figure 1 Trends in world energy consumption from 1970 to 2009. Total consumption in GJ is shown by the area plot (scale to the left) and per capita consumption in GJ/person is shown by the red line (scale to the right) (BP 2010).

improvement has not been rapid enough to achieve similar reductions in CO_2 per person (the product of the last three terms above), leading to increases in total global CO_2 emissions.

Even as efficiency acts to drive down energy consumption per economic output, demand for energy continues to rise. Yet, despite rising consumption and concerns that fossil fuel resources are diminishing, proved petroleum reserves have steadily grown over the past 40 years. With the rapidly increasing use of hydraulic fracturing and horizontal drilling, world natural gas proved reserves have also increased by more than a factor of two since 1980 (BP 2010).

With UN population projections estimating nearly 10 billion people by 2050, the demand for the transportation, cooking, heating, cooling, manufacturing, and other services provided by energy will likely remain strong. However, the ability of fossil energy to meet these demands will be impacted by a number of factors, including the extent to which climate-related environmental impacts become more pronounced and if GHG mitigation strategies are adopted.

Fossil fuels are expected to continue to play a major role in the global energy system for the foreseeable future, even if major GHG reduction policies were to be adopted worldwide. The recent World Energy Outlook published by the International Energy Agency (IEA) noted that if current international GHG policy commitments (e.g., those announced at recent climate meetings in Copenhagen and Durban) were to be implemented in full, global energy demand would still increase by 33% from 2010 to 2035. In this scenario, fossil fuels will still make up 75% of primary energy consumption in 2035, representing an increase in total worldwide fossil fuel consumption of about 25%. IEA estimates that if major commitments were to be made to limit atmospheric GHG emissions, overall fossil fuel consumption would fall, but natural gas consumption would still increase over the same time period (IEA 2011). It remains crucial, therefore, to understand the potential vulnerabilities of fossil fuel resources in a future affected by impacts of climate on the environment and the implementation of GHG mitigation policies.

3.02.1.2 Environmental and Social Variables That Influence the Use of Fossil Fuels

The possible adoption of policies to limit carbon emissions and the potential cost of such policies are not the only variables that influence the use or vulnerabilities of fossil fuels. Growing global populations demand more energy. Rising consumption and expectations in emerging economies (particularly China, India, Brazil, and Russia) are driving major increases in demand for energy-intensive products and services, particularly freight and personal transport (IEA 2011). Greater affluence also enables populations to consume more energy-intensive foods, such as beef (McAlpine et al. 2009). As populations grow more affluent, they also place greater value on environmental quality (Franzen 2003). Together, these factors act to drive up demand for fossil energy (given the nearly exclusive use of fossil fuels in the transportation and agricultural sectors) but (at least in the longer term) also place greater environmentally oriented constraints on how fossil fuels are produced and used.

3.02.1.3 Increasing Complexities and Costs of Resource Exploitation

As the demand for fossil fuels has grown, resource production and transport has expanded into increasingly challenging environments (e.g., deep sea and Arctic) and has required development and application of more advanced and more expensive technologies to meet that demand, particularly for petroleum. Financial, management, and regulatory structures supporting fossil fuel exploitation have also grown more complex as investors seek to maximize returns on investments and governments seek to maintain health and environmental protection goals. The growing complexity of the technologies and human systems needed to develop and exploit fossil fuel resources means that the investments, both in terms of finances and energy, needed to produce the next increment of fossil fuel energy continue to grow. As fossil fuel markets become increasingly global, the increasingly complex and expensive measures needed to meet demand and make up for reduced output from easily accessed resources means that it is likely that we have reached 'the end of cheap oil' (IEA 2011).

3.02.1.4 Climate: New Problems, New Responses

In addition to the above global-scale changes and pressures on fossil fuel resources, a change in climate would create further challenges. As resource production moves into environments that are increasingly difficult in which to operate, changes in environmental conditions can exacerbate the financial and technical challenges of resource extraction. Although there is a tremendous amount of experience with fossil fuels in a wide range of environments, decadal-scale changes in weather patterns could alter those environments in fundamental ways, resulting in operating conditions that are outside the ranges for which systems were designed. These problems include permafrost thawing, greater variability in weather (including more extreme conditions), and significant changes to precipitation patterns that could lead to drought in some areas and more severe and extensive flooding in others. These issues will require new technical responses to maintain the production and use of fossil fuel energy, independent of the potential application of carbon emissions constraints. In this particular instance, the term 'technical' covers more than just engineered systems, it also includes the financial, management, and regulatory systems necessary to enable the engineered systems to operate effectively.

3.02.1.5 Scope of Discussion

The focus of this chapter is on the vulnerability of fossil fuel resource extraction, delivery, and use to climate, in the context of the challenges posed by other global-scale changes. In general, fossil fuel resources are not affected by climate but the extraction, transport, and use of the resources are. One major use of fossil fuels, the generation of electricity from thermoelectric generating systems, is also vulnerable to climate, and so represents an additional source of vulnerability to the use of fossil fuels. Vulnerabilities of fossil fuels to GHG mitigation approaches will be discussed, with the focus on the extent to which those approaches have an impact on resources. The chapter will also discuss the different ways in which fossil fuels used in the transportation sector are vulnerable to climate, indirectly through vulnerabilities associated with an increased use of biofuels and electrification.

A common strategy among proposed GHG mitigation approaches is a focus on massive reductions in fossil fuel GHG emissions. If such changes in the global energy system were to occur, they would have similarly massive impacts on the form of the world economy. This chapter does not consider the vulnerabilities to fossil fuel use associated with changes to economies because of GHG mitigation strategies. However, it does recognize that the application of GHG emission reduction technologies would impact the use of fossil fuels, and these impacts are discussed at the scale of a single power generating plant. However, it is well beyond the scope of this discussion to address potential economy-wide impacts and the ensuing implications for fossil fuel use.

3.02.2 Vulnerability to Temperature Change

Fossil fuel production and use technologies have been designed to work within specific temperature ranges that account for variability and extremes of heat and cold. These ranges will, of course, vary with location and are impacted by latitude, altitude, surroundings, proximity to vegetation and water, and other factors. Most systems are able to operate even during short periods in which temperatures are outside the ranges of recent multidecadal measurements. However, energy production and use systems can be vulnerable to significant changes in temperature ranges or the duration and magnitude of extreme temperature episodes.

Although IPCC projected global changes in temperature are typically presented in terms of global averages, more important for energy system vulnerability are changes for specific regions and in the form of episodic events. Such changes could be substantial (Solomon et al. 2007). Local temperature characteristics are of most practical concern because they represent the conditions that determine design and operating parameters and are, therefore, the parameters of concern to decision makers. These local temperatures are influenced by the combination of a more complex set of factors than global average temperature, including alteration of atmospheric and ocean circulation patterns (e.g., El Niño-Southern Oscillation, Pacific Decadal Oscillation, etc.), local and regional land use and aerosol changes, and global temperature trends. In this chapter, 'temperature,' unless otherwise stated, refers to the local air temperature at the location of the energy resource.

Fossil fuel resources are vulnerable to these changes in ambient temperatures in several ways. For coal, the vulnerabilities to increasing temperature are primarily associated with thermoelectric power generation and are twofold: reduction in generating efficiency and increase in power demand. The vulnerabilities to natural gas include those associated with coal but may also include the impacts of thawing permafrost and the subsequent impacts to resource extraction and transport in the Arctic. Petroleum is similarly vulnerable to thawing permafrost.

3.02.2.1 Thermoelectric Cooling: Reduction in Efficiency

Increasing ambient temperatures adversely affect the thermal efficiency of thermoelectric generating systems. This means that there would be an increase in fossil fuels consumption (almost entirely natural gas and coal) if average temperatures increase. The temperature effect impacts Rankine (steam) cycle plants and Brayton (combustion turbine) cycle plants. Rankine cycle efficiency is most sensitive to higher condenser temperatures (and pressures) that result from increases in ambient air and water temperatures. Brayton cycle efficiency is most sensitive to higher inlet air temperatures, which require increased work to compress the air prior to fuel injection and combustion. In addition, increases in ambient temperature can also reduce the power output of combustion turbines (Daycock et al. 2004;

Wilbanks et al. 2008). Wilbanks et al. (2008) suggest that increases in ambient temperature from summer to winter could lead to reductions in power output of about 1–2% for coal and nuclear plants, and Daycock et al. (2004) suggest that power output could be reduced as much as 3–4% for each 10 °F in ambient temperature for combustion turbines.

In the near term, thresholds for Rankine plants would most likely be in the form of discharge water temperature limits, which are in place to prevent significant changes in ambient water temperatures that can harm local ecosystems. The probabilities of reaching these limits is high in some areas, illustrated by the fact that there have already been instances where plants were required to reduce production to avoid exceeding discharge temperature requirements and more are expected (Averyt et al. 2011; Beshears 2007; O'Grady 2011). Over the longer term, measures to adapt thermoelectric power generation cooling systems to increasing ambient temperatures would likely be coupled with measures to adapt to changes in water availability, which will be discussed in more detail below.

3.02.2.2 Temperature-Driven Demand

At the same time, electricity demand is sensitive to higher temperatures due to increased use of air conditioning during hot days (Amato et al. 2005; Miller et al. 2008; Wilbanks et al. 2008). Higher temperatures lead to greater use of air conditioning and electricity demand, which is usually met with peaking units that tend to be less efficient than base load generating plants. In addition, because air conditioning load increases occur during the same high-temperature periods that lead to decreased thermal efficiency, the result is that peak loads can coincide with periods when the generating efficiency is at its lowest. Conversely, higher temperatures also reduce the winter demand for heating, which tends to reduce consumption of fossil fuels, particularly natural gas (Amato et al. 2005). However, it is important to understand that the relationship between temperature and energy use can considerably vary with location. A 2001 analysis estimated that a local annual average temperature increase of 2 °C would result in an increase of per capita electricity consumption of about 12% in Florida, but a decrease of about 7% in Washington, DC (Sailor 2001).

3.02.2.3 Thawing of Permafrost and Impacts to Infrastructure

Temperature changes have particular importance in the Arctic. This is because of the growing importance of the Arctic as a source of fossil fuels (Gautier et al. 2009; IEA 2011) and because average temperatures in the Arctic are forecast by some to increase much more than the global average (Anisimov et al. 2007). The Arctic is addressed here as distinct from the Southern Hemisphere polar regions for two reasons. First, there is considerable energy infrastructure and potential for additional development in Arctic regions (Johnston 2010). Second, there is no analogous development in the Antarctic, due to an international treaty prohibiting such development on Antarctica (Antarctic Treaty 1991) and to the comparatively small land mass south of 40° S latitude.

Rising Arctic temperatures would have a direct impact on the accessibility to onshore fossil fuel resources. Roads are built directly on permafrost in tundra regions. Because tundra is unable to support the weight of vehicles when thawing occurs at the surface, vehicle access is physically limited by the inability of the ground to support vehicle traffic. Access is also limited by regulations that designate conditions under which resource exploration is permissible to avoid permanent damage to the permafrost. As seen in Figure 2, the permissible days of exploration have dropped from 200 to about 100 days per year between 1970 and 2003 as temperatures have increased, making it increasingly difficult, if not impossible, to conduct effective exploration activities (Arctic Climate Impact Assessment 2004; Wilbanks et al. 2008). In addition, permafrost has been relied upon to support other key infrastructure, including the Trans-Alaska Pipeline System (TAPS). The TAPS design recognized the potential for degradation and even liquefaction of the ground supporting the pipeline, and design and operational measures have been incorporated into the system to avoid spills associated with subsidence caused by heating of the permafrost. A 2003 study noted that, while neither the TAPS operator nor the relevant regulatory authority considered permafrost degradation to be a problem, the design was based on a temperature history that covered one of the coldest 20 year periods in modern Alaskan history (U.S. Arctic Research Commission Permafrost Task Force 2003). The same study also noted that the oil and natural gas pipeline networks in western Siberia appear to be at even more risk to temperature-driven permafrost damage than the TAPS.

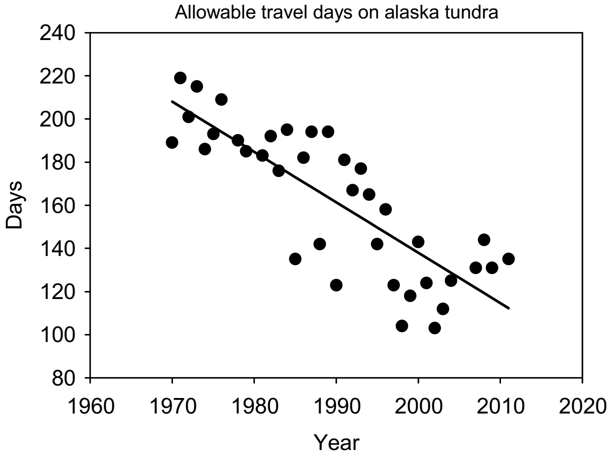

Figure 2 Decline in Alaska winter travel days from 1970 to 2011. Through 2003, opening dates reflect general travel opening. After 2003, opening dates reflect partial travel opening (Eastern Slope region). From Arctic Climate Impact Assessment, 2004: *Impacts of a Warming Arctic: Arctic Climate Impact Assessment*. Cambridge University Press, Petroleum News (2011): Off-road travel closes on North Slope. May 29, 2011, Petroleum News, Anchorage, AK. Retrieved February 17, 2012. [Available online at http://www.petroleumnews.com/pntruncate/230159208.shtml.]

3.02.2.4 Increased Access to Arctic Resources

Increasing temperatures in the Arctic would have a potentially beneficial impact on fossil fuel resources. The Arctic Climate Impact Assessment estimated that a reduction in Arctic sea ice could result in 90–100 navigation days per year (at 50% sea-ice concentration), or as many as 150 navigation days per year for ships with ice-breaking capacity in seas of up to 75% sea-ice concentration (Arctic Climate Impact Assessment 2004). Such an increase in navigable days (from the current 20–30 days at 50% sea-ice concentration) would greatly expand resource accessibility from sea routes. The combination of increased access by sea and difficulties with supporting onshore infrastructure cited above make it unclear if, or to what extent, temperature increases in the Arctic might enable increased offshore petroleum and natural gas production. Even so, there is a focused effort, particularly in Russia, to increase production and export of Arctic hydrocarbon resources, to the extent of the launch of the world's first ice-breaking oil tanker (Johnston 2010).

More generally, it is important to recognize that energy production in the Arctic is a clear example of the expansion of energy resource exploration and production into increasingly severe environments. While increasing temperatures have one set of impacts, decreasing temperatures have their own impacts. Colder temperatures or more severe storms (such as the one experienced in early 2012) can substantially hinder transportation and operations in the Arctic. Fossil fuel resources in the Arctic remain vulnerable to climatic conditions, whether warmer or colder, for which transportation and energy infrastructures are not adequately designed.

3.02.2.5 Responses/Recommendations/Thresholds

The extent of current understanding is not sufficient to identify a specific threshold beyond which responses to increased ambient temperature would need to be significantly different from current practices. However, operating plans and plant designs must be aware of the potential for long-term changes in the range of local ambient temperatures compared to historical averages. The primary approach to reducing the effects of temperature-driven demand is to improve energy end use efficiency in general (Wilbanks et al. 2008). Although this approach does not specifically address peak loads associated with temperature, it does reduce load in general, including peak load. Greater use of passive heating and cooling and more energy efficient building stock can specifically reduce space conditioning loads and use of demand-side management (DSM) that allows cooling systems to be cycled across a large portion of the affected distribution system and also allows some loads to be entirely shut down, which is also an adaptive approach to managing peak loads (Miller et al. 2008). Comprehensive approaches to DSM may be more effective if utility efforts are combined with government incentives or mandates (Carley 2011). These policies may take the form of energy efficiency incentives and changes to building codes to promote efficiency. Although DSM can result in lower total and peak demand, there remain challenges to broad implementation, including a need for improved metering and information infrastructure and changes in utility operational practices (Strbac 2008).

3.02.3 Weather Extremes

Weather extremes, such as severe tropical and other storms, intense precipitation events and flooding, and drought, can create vulnerabilities to the use of fossil fuels. A number of studies have indicated that the frequency and intensity of these events may increase as a consequence of changes in the global climate (Easterling et al. 2000; IPCC 2011). Observations suggest that there has been an increase in heavy precipitation events over the past several decades compared to earlier periods, albeit with strong regional variations (Gutkowski et al. 2008; IPCC 2011). However, there is also considerable uncertainty associated with these estimates and the impact of such changes, particularly with regard to magnitude of the changes, variability, and local impacts (IPCC 2011; Pielke and Wilby 2012). Even with these uncertainties, the IPCC recently reported that is it *likely* (The IPCC defines 'likely' as having a 66–100% estimated likelihood of the outcome) that, as a consequence of climate change, (a) the frequency of heavy precipitation will increase; (b) the maximum wind speed of tropical cyclones will increase; and (c) the 'global frequency of tropical cyclones will either decrease or remain essentially unchanged.' They also report that there is *medium confidence* (The IPCC defines 'medium confidence' as 'about 5 out of 10 chances' of occurring.) that (a) droughts will intensify in the twenty-first century and (b) there will be increases in heavy precipitation in spite of projected decreases in total precipitation in some regions (IPCC 2011).

Despite the significant uncertainties in future weather extremes there is a potential increase in risk due to increased precipitation, drought, and tropical cyclones as a result of climate change. It is, therefore, prudent to develop risk management strategies to address the vulnerabilities to fossil energy associated with weather extremes.

3.02.3.1 Drought

In many locations, the onset of drought conditions would exacerbate the shrinking gap between population-driven demand for water and water availability. The southwestern United States is a relevant example of these interactions. Even as an 11-year drought has reduced the levels of major reservoirs in the region, the population of the intermountain states (Arizona, Colorado, Montana, Nevada, New Mexico, Utah, and Wyoming) has increased by 20% since 2000 and is projected to increase nearly 40% more between 2010 and 2030 (Environmental Defense Fund and Western Resource Advocates 2010; U.S. Census Bureau 2005). Climate modeling indicates that conditions in the southwestern United States may become drier. In the event that the modeled results are realized, the resulting drought would add to the already growing stress on water resources (Environmental Defense Fund and Western Resource Advocates 2010). Even without such long-term trends resulting from human intervention in the climate system, the natural record of drought (e.g., such as the multidecadal drought in the western United States in the sixteenth century) already suggests that the threat of prolonged dry periods is significant (Meko et al. 2007).

More immediately, the Electric Reliability Council of Texas (ERCOT), operators of the electrical grid in Texas, recently released an assessment that indicated a potential shortage of more than 1000 MW of power during the winter of 2011–12 if the drought in Texas had continued unabated, even if load levels and unit outages remained at historical levels (ERCOT 2011). In addition to lack of water availability due to drought, reduced river flow in drought conditions can also lead to restrictions on thermoelectric cooling water discharges, as was seen in Europe during the 2003 heat wave (Fink et al. 2004; Förster and Lilliestam 2010).

3.02.3.1.1 Competition for Water Resources

More broadly, increasing populations and growing demand for energy will increase competition for water resources. Thermoelectric power generation accounted for 41% of all withdrawals of fresh water in the United States in 2005, more than any other sector (Kenny et al. 2009). Although a small fraction of the withdrawn water is actually consumed (e.g., not available for further use), thermoelectric power generation requires large volumes of water to operate (USDOE 2006). Drought conditions can, therefore, be a source of vulnerability for fossil-fueled power steam plants, in addition to the temperature vulnerabilities noted above. In the event that carbon capture systems are used for fossil-fueled plants, the water demands could substantially increase (Zhai and Rubin 2010). The need for large volumes of water for conventional cooling systems could limit the location of future fossil-fired power plants, particularly in regions that are projected to face greater vulnerability to drought driven by climate change.

Production of natural gas using hydraulic fracturing requires significant amounts of water for the fracturing process. Volumes of required water vary from about 3 million to 8 million gallons per well completion, depending on specific well conditions (Bene et al. 2007; Hazen and Sawyer 2009). Some estimates of well completion activity indicate that the fraction of groundwater used for hydraulic fracturing could reach near 50% of total groundwater withdrawals. In locations vulnerable to drought, such levels of water use could adversely impact the viability of gas production from tight formations.

Unconventional sources of petroleum could also be adversely impacted by drought. A recent study estimated that transportation fuels produced from coal, natural gas, oil shale, or tar sands could require 150–270% more water per gallon of fuel produced than conventional petroleum-based gasoline (King and Webber 2008). Because many of these resources are located in areas vulnerable to drought, water availability problems have the potential to make these proposed approaches to liquid fuel production nonviable. Much of the analysis related to these unconventional fossil fuel resources, particularly for development in the western United States, was conducted 30 or more years ago, and growing populations and other demands for water in the interim have made it difficult to evaluate the validity of those earlier studies (Bartis et al. 2005). In the event that long-term average precipitation levels were to fall, the stresses on regional water resources would increase, further limiting the ability to produce these unconventional energy resources.

3.02.3.1.2 Energy Requirements for Constrained Water Supplies

Drought would also be likely to increase the amount of energy that is required to meet the demand for water in afflicted regions. A 2002 report by the Electric Power Research Institute estimated that the electricity required for supplying treated water in the United States would closely track population growth, which resulted in a projection that the fraction of electricity required for water supply and treatment would remain relatively constant at about 4% of total generation (EPRI 2002). However, this assumes little fundamental change in water resources. In the event that there are significant water shortages due to drought, the energy required to supply and treat water could substantially increase, perhaps as much as a factor of four times more energy per unit volume of water (Environmental Defense Fund and Western Resource Advocates 2010). Such increases would be expected to be regional rather than national but have the potential to add to the demand for fossil-fueled electricity.

3.02.3.2 Flooding; Infrastructure Vulnerability

The proximity of numerous power generation facilities, mines, roads, railroads, and other energy-related infrastructure to rivers, combined with the multidecadal operational lifetimes of those facilities, makes it crucial to account for the potential vulnerability of energy-related facilities to floods. As examples, the floods across eastern Australia in late 2010 through early 2011 resulted in an estimated reduction of 15 million tonnes of coal output (ABARES 2011) and the 2010 Pakistani floods were estimated to have knocked nearly 15% of the country's electricity generating capacity off line (Kronstadt et al. 2010). Although an increased frequency of heavy precipitation events implies increases in local flooding, differences in regional and local factors result in complex relationships between precipitation and flooding, leading to the IPCC forecasting with *low confidence* (The IPCC defines 'low confidence' as having 'about 2 out of 10 chances' of occurring) that fluvial flooding would increase in general as a consequence of climate change (IPCC 2011). Even so, the same IPCC report assumes that, based on physical reasoning, there is medium confidence that local flooding would increase.

3.02.3.3 Storm Intensity and Frequency

Experience with Hurricane Ivan in 2004 and Hurricanes Katrina and Rita in 2005 demonstrated the vulnerabilities of offshore petroleum production to powerful tropical storms (see Figure 3). Over 100 production platforms were destroyed and more than 600 pipelines were reported damaged in the Gulf of Mexico by the two 2005 storms (Det Norske Veritas 2007). The loss of production capacity and damage to other energy infrastructure caused by these two storms is estimated to have cost $15 billion in direct losses, not including restoration and

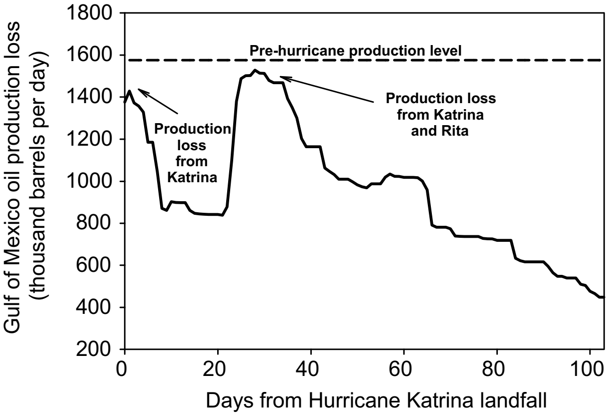

Figure 3 Loss of petroleum production due to damage from Hurricanes Katrina and Rita. From Energy Information Administration (2005): Hurricane Impacts on the U.S. Oil and Natural Gas Markets. Washington, DC, U.S. Department of Energy, Energy Information Administration.

recovery costs, or the direct and indirect costs of higher prices to consumers (Wilbanks et al. 2008).

In addition to damage to production infrastructure, US refining capacity is also highly vulnerable to damage from tropical storms, with nearly 45% of crude oil refining capacity located in Louisiana and Texas, primarily along the coast of the Gulf of Mexico (Energy Information Administration 2011a). The consequences of such concentration of refining capacity in an area prone to tropical storm damage were clearly seen following the impacts of Hurricanes Katrina and Rita (Hibbard 2006; Parfomak 2008; Wilbanks et al. 2008). The vulnerabilities to storm damage go beyond direct impacts to refineries to include the potential for reduced output as a result of loss of electric power caused by damage to electric generating plants or transmission lines (Peters et al. 2006).

There has been considerable study of the potential impact of climate on the intensity and frequency of tropical and other storms. Although there is general agreement that a warmer global climate would increase atmospheric and sea surface temperatures and the amount of water in the atmosphere (Solomon et al. 2007), which are associated with more powerful storms, there remains substantial uncertainty about the ultimate effect on storm frequency and intensity (Gutkowski et al. 2008; IPCC 2011).

3.02.3.4 Responses/Recommendations

It is reasonable to view Hurricanes Katrina and Rita as threshold events that demonstrated actual, as opposed to probable, vulnerability to intense storms. Following the 2005 storms, efforts were made by industry to develop improved standards for offshore platforms (American Petroleum Institute 2005) and to improve capabilities to repair damaged undersea pipelines (Bicker 2010), which were demonstrated during the Macondo oil spill in April 2010. These efforts can help reduce vulnerabilities to tropical storm events, but can in no way eliminate them. The concentration of energy infrastructure along the US Gulf Coast (or elsewhere) is even more difficult to address, given the enormous capital investments in existing infrastructure and the long time frames associated with development of new infrastructure. A recent study identified policies that could be applied to encourage geographic dispersion and infrastructure recovery from disruptions, but noted that such policies are not without their own risks (Parfomak 2008).

The vulnerabilities to weather extremes discussed here are primarily related to infrastructure. The approach to minimizing the impacts of weather extremes is generally twofold. The first and most important step is to consider the potential range of extremes (e.g., temperature, flooding, and drought) that may be experienced over the lifetime of the facility or system and to design the facility or system to minimize the risks associated with the relevant extremes. Although the focus here has been on infrastructure, it is crucial for designs to protect workers and the public from harm due to extreme weather events. The second step is to develop and implement effective emergency response plans to guide responses in the event of weather extremes. Effective design and planning can mitigation long-term impacts associated with extreme weather events.

3.02.4 Sea Level Rise

A rise in the mean sea level represents a vulnerability to facilities and infrastructure located along coastlines. The risk associated with sea level rise is magnified by the fact that major impacts of coastal inundation are experienced as a consequence of high tides and storm surge. The combination of more intense tropical storms and higher base sea level could result in significantly greater coastal areas being subject to higher levels of inundation than have historically occurred.

There is general agreement that the observed rise in mean sea level between 1961 and 2003 would continue if global temperatures increase, caused by melting land ice and the thermal ocean expansion (Bindoff et al. 2007). The IPCC's recent report on managing risks of extreme events predicts that it is *very likely* (The IPCC defines 'very likely' as having a likelihood of 90–100% probability of occurring) that increasing sea level will contribute to 'upward trends in extreme coastal high water levels in the future' (IPCC 2011). The IPCC predicts mean sea level to rise between about 0.2 and 0.6 m in the last decade of this century (Meehl et al. 2007). The IPCC predictions for sea level rise do not include substantial contributions from loss of ice from the Greenland or Antarctic ice sheets. These predictions have been questioned since the publication of the IPCC's Fourth Assessment Report, with some studies hypothesizing that ice sheet loss could increase the magnitude of sea level rise by the end of the century by a factor of 2–3 (Nicholls et al. 2011; Rignot et al. 2011).

3.02.4.1 Infrastructure Vulnerability

The vulnerabilities to sea level rise are similar to those noted above for flooding. Fossil plants, refineries, fuel loading ports, and related infrastructure located in coastal areas would be vulnerable to higher sea levels and to inundation during extreme weather events such as tropical storms. Higher sea level will, therefore, likely increase vulnerability to these events for facilities in coastal areas. Sea level rise would not add to risks for those facilities that are located away from coastal regions, although loss of coastal facilities, even on a temporary basis, would be expected to increase the stress on unaffected capabilities (as would also be the case for weather extremes separate from sea level rise). An additional risk related to sea level rise is the increased potential for increased ocean front erosion. This could be a factor in the stability of transport infrastructure (roads, pipelines, etc.) in particular. Although it would generally be expected that any impacts would be relatively short term, there may be situations where loss of bridges or other major infrastructure components could result in much longer term impacts.

The probability of continuing sea level rise is considered to be high, as noted above. However, the probability of abrupt and major sea level rise, as has been suggested as a result of major collapse of ice sheets, appears at this point to be low, although the uncertainties of such events are substantial. There is not expected to be a specific point at which sea level rise is generally 'too high,' given the site-specific factors that determine vulnerability. It is more likely that there would be a threshold event, such as a tropical storm combined with high tides and a general rise in sea levels that would be identified after the fact, similar to the situation with weather extremes. The adaptation measures applicable to weather extremes and concentrated infrastructure hold for sea level rise as well, but may need to be supplemented with measures such as construction of sea walls. The recent disaster at the Fukushima nuclear plant highlighted the need for emergency systems, particularly emergency generators designed for inundation levels higher than those for the plant as a whole in the event that the sea wall was breached (Buongiorno et al. 2011). The massive flooding in Pakistan in 2010 (although not associated with sea level rise) and the resulting damage to the country's power generation capacity similarly illustrates the need to design energy infrastructure for resilience with respect to high water conditions in areas prone to sea level rise (Kronstadt et al. 2010).

3.02.5 Mitigation Strategies

Studies calling for reductions in CO_2 emissions from energy produced by fossil fuels as a means to address climate change first appeared in the mid-1970s (Marchetti 1977; Schneider and Dennett, 1975). The emphasis on global-scale GHG mitigation has grown in scope and contention, with many strongly stating that major mitigation measures are of the essence (IEA 2008, 2011; Princiotta 2011) and others questioning the need for such major changes to the world energy system and economy (Lomborg, 2001). Although a strong focus of many mitigation strategies is a shift toward nonfossil energy sources (e.g., wind, solar, nuclear) and a major effort to reduce energy demand in general, many (if not most) proposals continue to include fossil fuels as part of a strategy for reducing GHG emissions to levels considered necessary to avoid the most severe predicted impacts on climate from the addition of GHGs (Meinshausen et al. 2009; Rogelj et al. 2011). Any large-scale implementation of GHG mitigation strategies would substantively change the role of fossil fuels in the world energy mix with a general trend of 'decarbonization;' that is, moving toward less carbon-intensive fuels and technologies such as natural gas, coal with carbon capture and sequestration (CCS) systems, and vehicle electrification (IEA 2008; Pacala and Socolow 2004). Such changes would emphasize different vulnerabilities for different fossil fuels, presenting both opportunities and challenges.

3.02.5.1 Rate of Change in Energy System: Introduction of New Technologies and Practices

In general, GHG mitigation strategy proposals call for major, and relatively rapid, changes in the global energy system. In the near term, the lack, but continuing consideration, of binding global and national commitments to significantly reduce GHG emissions creates great uncertainty for those faced with making investment decisions for new energy infrastructure (Bergerson and Lave 2007; Patiño-Echeverri et al. 2009). Over the longer term, major changes in the energy infrastructure would be likely to increase system complexities by incorporating a much higher fraction of intermittent electricity generation sources, tighter links between the energy and agricultural sectors through increased use of biomass, and the addition of CO_2 transmission networks. The more rapidly these complexities are added, the more vulnerable the system is to unforeseen problems. Although it is questionable how quickly the energy system could be transformed (Kramer and Haigh 2009; Smil 2010), increasing the complexity and the rate of change in the energy system would represent a source of vulnerability to fossil and other energy sources.

3.02.5.2 Backup for Intermittent Generation Sources

One of the added complexities of a low carbon electricity generation system would be the intermittent nature of many existing renewable resources, particularly wind and solar energy. Because of their inherent intermittency, other demand dispatch-capable generating resources that can match demand and balance load characteristics – largely fossil-fueled generating systems – need to be maintained as backup for renewable resources. Renewable resources can reduce the total fossil-fueled power generation but may not reduce the required generating capacity (Hannes 2009). Indeed, there are estimates that fossil-fueled generating capacity may need to increase, even if total fossil-fueled generation decreases (Gowrisankaran et al. 2011). The combination of level or increased capacity (likely with short start-up or load ramping times) and lower overall utilization means that capital costs are likely to become a larger component of total cost of electricity for fossil-fueled units. This also complicates decisions related to maintenance and operational life.

3.02.5.3 Natural Gas and Potential for Methane Emissions

Natural gas is seen as a key component of many strategies to reduce GHG emissions from energy production and use. This is because of the significantly lower carbon content of the main component of natural gas (methane) and because of the ability of natural gas to be used in combined cycle generating plants that can reach considerably higher thermal efficiencies compared to Rankine-cycle steam generating systems. Until recently, a major concern regarding this approach was the limited global supply of natural gas. In the past several years, this concern has been greatly reduced with the increasing use of hydraulic fracturing and its ability to extract what is referred to as 'unconventional' natural gas from formations previously considered uneconomical to develop (Kerr 2010). More recently, there has been considerable controversy focused on the potential for substantial increases in GHG emissions due to the much higher level of methane emissions that can be released during completion and maintenance (called 'workovers') of unconventional natural gas wells (Howarth et al. 2011; Stephenson et al. 2011). Unconventional natural gas production has been highly controversial for other environmental reasons, largely associated with impacts to groundwater (Osborn et al. 2011). The vulnerability to natural gas related to climate, however, is largely related to fugitive methane emissions, which (in most cases) can be controlled using relatively straightforward available technologies.

3.02.5.4 Increased Rate of Utilization with Carbon Capture Energy Penalty

In addition to switching to natural gas, many CO_2 mitigation strategies propose use of technologies that capture CO_2

generated by fossil-fueled electricity generating plants and sequester it. There are two main approaches to CCS technologies – pre- and post-combustion systems. Pre-combustion system designs generally employ highly oxygen-enriched air (90% or more O_2) in combustion or gasification processes. These oxyfuel combustion systems are designed to burn coal or natural gas with oxygen that would generate a high-CO_2 exhaust gas that could be compressed and sequestered, potentially without extensive additional treatment. Oxygen-based gasification systems generate a high-hydrogen fuel for use in combined cycle systems that have essentially no CO_2 in the exhaust. Current post-combustion designs rely on amine-based scrubbing reagents to capture the CO_2 and then release it during reagent regeneration. These designs typically require substantial reheating of the flue gas. Both pre- and post-combustion carbon capture designs therefore require large amounts of heat and electrical energy, which would decrease the net power generation for the same amount of fuel input. While additional energy would be needed to compress, transport, and inject the captured CO_2, that energy is small relative to the energy needed for the carbon capture processes. Estimates of the efficiency penalty are in the range of about 15–25% or about 5–10% points, depending on the plant design (House et al. 2009; Rubin et al. 2007). Conventional pulverized coal systems would suffer the largest penalty, with integrated gasification combined cycle systems having the lowest efficiency penalty for CCS.

The vulnerabilities to fossil fuels from broad adoption of CCS are threefold. First, the significant reductions in efficiency mean that greater amounts of coal or natural gas would be required to generate the same amount of net electricity. This would increase the rate of resource depletion and would also increase the environmental impacts of the extraction processes. Second, the demand for water would increase because of both the lower net thermal efficiency and because (for post-combustion systems) CCS process designs now depend on substantial amounts of water in addition to that for thermoelectric cooling (Ciferno et al. 2010). The third vulnerability is that the cost of electricity from fossil-fired plants would increase, due to greater capital investment requirements as well as increased operating costs, which would make nonfossil alternatives more attractive. It is also possible to view CCS as increasing the potential use of coal in particular, in the event that GHG emission limitations were to be implemented, as the process would substantially reduce the emissions of CO_2 from coal-fired power generation.

3.02.5.5 CCS Geological Storage Risks

Once the carbon is captured, it would need to be sequestered to remove it from the carbon cycle. Injection of compressed CO_2 into underground geological formations, such as depleted petroleum reservoirs or deep saline aquifers, is currently considered to be the most likely method and has been demonstrated at large pilot scale. Such efforts would not be without risks, including risks associated with CO_2 leaks into the atmosphere, contamination of groundwater resources, or induced seismicity (Wilson et al. 2007). Although the US Department of Energy has developed a research and development roadmap that recognizes many of the risks related to geological sequestration, fossil-fueled power generation systems would remain vulnerable to these as well as legal and financial risks, particularly the issue of long-term liability for sequestered CO_2 (USDOE 2007).

3.02.5.6 Increasing Electrification of Transportation System

While increased cost of electricity will tend to reduce demand, the growth of electric-capable vehicles, including all-electric and plug-in hybrid electric vehicles, will act to increase electricity demand. This increased demand, if it substantially increases, would likely have its own load pattern, typically expected to be opposite of the current daytime peak, since it is generally believed that electric vehicles will recharge at night when total demand (and rates) are lower. However, there would also be the potential to 'impact the overall system reliability when the entire infrastructure is used near its maximum capacity for long periods,' according to one study (Kintner-Meyer et al. 2006). The study also noted that, if the current cyclical load patterns were to change such that base loads were largely constant over a 24-h period, maintenance scheduling could be more difficult. Conversely, it has been noted that significant vehicle electrification could serve as a very large electrical energy storage system if grid controls and capabilities are in place. The highly dispersed battery capacity in such a situation has been proposed as a means to store intermittent renewable electricity and to provide a stabilizing influence on grid operations (Kempton and Tomić 2005).

3.02.6 Adaptation

Measures taken in response to climate can also create vulnerabilities for fossil fuels, even if those measures are implemented in areas other than energy. Adaptation measures may include responses to drought such as the need to transport water greater distances or employ desalinization systems, both of which will increase the demand for energy now largely supplied by fossil fuels. Relocation of infrastructure away from areas that are increasingly prone to flooding has the potential to disrupt operations of pipelines, power plants, refineries, and other energy system components. Shifts in populations to cooler climate zones or away from flood zones would lead to changes in transportation energy needs or electricity demand patterns. Similarly, if agricultural regions shift toward more favorable growth zones, the transportation infrastructure and possibly energy requirements could also shift.

The impacts to fossil fuels of other adaptation measures have been discussed above. These include increased air conditioning load and the potential for ensuring adequate water supplies using more energy-intensive measures. In both cases, the vulnerability to fossil fuels is an increased rate of resource consumption.

One issue that was not addressed in the above discussion of increased temperature is the potential for greater formation of tropospheric ozone. There is a recognized link between increased temperatures and increased formation and concentration of tropospheric ozone (Weaver et al. 2009). To the extent that climates become hotter, tropospheric ozone concentrations are likely to increase, although the links between climate (which involves more than simply temperature change) and ozone formation are more complex than a simple linear relationship between temperature and ozone (Jacob and Winner 2009; Steiner et al. 2010). Even so, in instances where air quality problems worsen as a consequence of climate, the adaptation measure needs to be able to reduce anthropogenic sources of ozone precursor emissions, particularly nitrogen oxides, much of which are emitted by the combustion of fossil fuels. This pressure could expand the need for pollution control technologies and strategies, which could impact the use of fossil fuels.

3.02.7 Social Impacts

Vulnerabilities of fossil fuels to climate are not entirely related to direct physical climate impacts or changes in technology, but also include what are broadly defined here as 'social impacts.' These can include corporate and personal behavior and perspectives or political instability that may be caused by or exacerbated by changes in climate.

3.02.7.1 Changes in Personal and Corporate Behaviors

Personal and corporate behaviors related to energy could result in reduced demand for fossil fuels as people and organizations respond to changes in climate. Voluntary measures, such as reducing heating, ventilating, and air conditioning energy consumption, purchasing more fuel efficient vehicles, or greater use of public transportation can have significant impacts on energy consumption. Although these changes may be primarily driven by increases in energy prices (Busse et al. 2009), changes may also be motivated by other than explicit economic factors (the converse is also true – individuals and organizations may also opt to take no action, even when action can be economically profitable). The McKinsey study, 'Pathways to a Low-Carbon Economy' identified significant financial savings and GHG reductions due to behavioral actions to reduce energy use (McKinsey and Company 2009), even in the commercial and industrial sectors, which would be expected to have the technical and financial wherewithal to take advantage of efficiency opportunities.

The extent to which behaviors pose vulnerabilities to fossil fuels is uncertain. On the one hand, it is possible to argue that reduced consumption can harm the financial health of the fossil fuel industry. On the other hand, considerable resources are being applied by electricity generating firms to enable individual and corporate consumers to reduce consumption, particularly during periods of peak demand, which can help utilities avoid or delay the need to operate – and finance – peak generation equipment or purchase additional expensive peak power from other generators (U.S. Department of Energy 2006).

3.02.7.2 Siting Energy Infrastructure

There are many connections between technological systems (that tend to be the focus of technical and policy development) and social and political 'systems' such as communities, citizen groups, and political organizations that can greatly influence the success of technological strategies. If the concerns of these social systems are not adequately recognized, understood, and addressed, the vulnerability of technological approaches to delay or increased cost from political or legal challenge substantially increases. Siting of energy infrastructure, including energy extraction, pipelines, generating plants, or carbon storage facilities, can be one of the more difficult practical barriers to the development, demonstration, and deployment of energy system components.

Switching from coal to natural gas has been considered as an important component of GHG mitigation strategies (IEA 2008; Pacala and Socolow 2004). Recent advances in natural gas production technologies, particularly the combination of hydraulic fracturing and horizontal drilling, have substantially increased proven natural gas reserves. However, the use of hydraulic fracturing has become highly controversial due to concerns about the potential environmental impacts of the process. Although the controversies are most visible in the general news media, citizen group websites, and even documentary films, they are also debated in the scientific literature (Davies 2011; Osborn et al. 2011; Schon 2011). These concerns are serious enough that there are active efforts to ban the use of hydraulic fracturing in some localities, despite the potential for significant personal and community economic benefit (Tavernise 2011).

Public concerns also impact the ability to develop and demonstrate CCS technologies, a critical component of most comprehensive GHG mitigation approaches. There are examples of local-, state-, and even federal-level agencies refusing to allow carbon sequestration projects to move forward because of public opposition (Brown et al. 2011; Kanter 2011).

Although there is a tendency for technical and policy experts to simply attribute such opposition to a 'not in my backyard' attitude, there are approaches that can be taken to address public concerns. The public concerns are often different from those perceived by the technical and policy experts, indicating that different communication and outreach approaches are needed to develop beneficial relationships with the communities and other social organizations that are impacted by energy infrastructure (Bradbury et al. 2009; Oltra et al. 2010; Wong-Parodi et al. 2011). Although there is extensive research and literature on the need for public engagement in the development and use of energy-related science and technology, there often seems to be much less application of that understanding in practice.

3.02.7.3 Political Instability

Political instability and conflict in major oil-producing regions have long been seen as sources of vulnerability to petroleum supplies. Conflicts in the Middle East, in particular, have repeatedly demonstrated that world oil prices, and in some instances, availability, are subject to disruption during times of conflict. Already-tight supplies of water in the Middle East will be increasingly stressed by growing populations. Changes in precipitation patterns, combined with existing political tensions and water demands, could easily increase the chances of conflict, with a substantial potential for petroleum supply disruption (Chin 2008; CNA 2007; Gleick 1989). Conflict and instability are not restricted to the Middle East or other regions of historical concern. There is also a growing potential for conflict over Arctic resources that could impact fossil energy resources particularly if those resources become more accessible, as discussed above (Johnston 2010; O'Rourke 2011).

3.02.8 Systemic Impacts

Changes to the global energy system in response to climate and energy security concerns and the increasing technical challenges of accessing fossil energy resources have led to greater complexity in the system. A greater emphasis on biofuels in the United States, for instance, has more closely tied the stability of the US transportation fuel supply to the uncertainties in agricultural output that are strongly influenced by changes in precipitation and temperature. The extent to which, and the rate at which, the energy system, including fossil fuels, will be required to change to mitigate GHG emissions can increase the potential for unforeseen problems and vulnerabilities.

3.02.8.1 Increasing Electrification: Pressures on Generation, Transmission, and Distribution

Increasing electrification of light-duty vehicles is seen as a key component of a comprehensive GHG mitigation strategy, as well as a means to reduce dependence on imported petroleum. A major shift toward electrified vehicles, as noted above, can place greater pressures on generation, transmission, and distribution systems. It is unclear whether the transportation system is at greater risk due to reliance on long, and often politically uncertain, petroleum supply chains compared to increased electrification of the vehicle fleet.

3.02.8.2 Shifting Toward Petroleum if Alternatives are not Successful

One vulnerability faced by fossil fuels is the potential for greater petroleum demand, should renewable fuel or electrification options fail to displace petroleum as much as expected. Although this vulnerability may also apply to electricity generation, it may be most pressing for transportation fuel. In 2009, ethanol production in the United States reached 10.6 billion gallons, compared with the consumption of 127 billion gallons of gasoline (Energy Information Administration 2011b; RFA 2011). A significant drop in ethanol production, conceivably due to climate-related reductions in feedstock production or disruption in transport due to flooding, could place considerable stress on the gasoline production infrastructure in the United States. A recent analysis estimated that the use of ethanol resulted in US retail gasoline prices being lower by an average of $0.89 per gallon in 2010 (Du and Hayes 2011); it is tempting to presume that major reductions in the availability of ethanol would increase retail gasoline prices the same amount. Even if such a presumption were to be accurate (which is questionable), transportation fuel shortages have significant costs to the economy beyond higher fuel prices.

3.02.8.3 Technological Change

More generally, major changes to the energy system designed to lower carbon emissions in a relatively short period of time could increase risks due to unforeseen consequences of those changes. It is recognized that technical failures often accompany innovation, often because innovation often moves technological systems beyond well-developed design and operational experience (Chiles 2001; Petroski 1992). Although technology developers work to create systems that are robust, the relatively rapid introduction of new technologies and the increasingly tight coupling of complex systems (e.g., agriculture and energy, water and energy) can combine to have unforeseen impacts, both beneficial and adverse. The nature of unforeseen events is such that they are impossible to specifically address *a priori*. Even so, it will be important to develop systems for both fossil and other energy resources that are as robust as possible as the transition to a low-carbon energy system progresses.

3.02.9 Conclusions

To many, the greatest vulnerability of fossil fuels to climate is a shift toward a carbon-constrained energy system. There are calls for, and analyses of, global efforts to achieve significant carbon emission reductions, including reductions to zero net carbon (DeCanio and Fremstad 2011; Jacobson and Delucchi 2011; Kharecha et al. 2010). The practicality of such reductions to be achieved in practice due to technical, economic, social, or political barriers remains an open question, but one that has generated enormous political and public debate.

Regardless of the status of national or global efforts to reduce carbon emissions, fossil fuels are also vulnerable to changes in climate and the ensuing impacts to resource production. Because fossil fuels will necessarily continue to be a part of the global energy system for the foreseeable future, it is important to understand those vulnerabilities that are driven by climate in addition to its other environmental and social vulnerabilities. Changes in temperature and precipitation patterns could necessitate changes in fuel production practices and, potentially, accessibility to resources. The impacts of environmental change more broadly have a strong potential to exacerbate existing, or lead to new, political tensions that can impact the production and transport of fossil resources. These conditions, now considered to be anomalies, may well become conditions that need to be addressed on a continuing basis.

The growth of international trade, tighter connections between different components of the global energy system, and an increasing emphasis on development of sustainable practices will bring a greatly expanded emphasis on understanding system-wide and life cycle impacts of corporate, national, and international strategies regarding the production and use of fossil fuels. Questions regarding the life cycle emissions from natural gas and life-cycle GHG comparisons between petroleum and biofuels are two examples of the growing policy relevance of life cycle analysis, particularly with regard to GHG emissions and climate response policies. The 'Green Book' recently released by the National Research Council recommended that the US Environmental Protection Agency incorporated sustainability concepts (i.e., a bottom-up vulnerability perspective) into its policy development and implementation (National Research Council 2011). The growing trend toward addressing problems from a sustainability perspective will increase the need for understanding the combined environmental, economic, and social impacts associated with issues such as energy production and use that have previously been evaluated from perspectives that were narrowly focused on individual technical, economic, or environmental factors.

For most of the issues addressed here, there are few, if any, distinct physical thresholds that will clearly define a transition from one set of conditions to a 'new normal.' In many instances, thresholds may be organizational rather than physical, as organizations perceive the need to prepare for changes in conditions associated with climate, or as financial, legislative, or regulatory requirements require organizations to take action in response to changing conditions (Lehmann 2011). Regardless of whether there are physical, organizational, or no thresholds, the impacts of climate can create additional factors that will impact the ability to develop and use fossil fuel resources. It is important to remain aware of how conditions are changing and how they are expected to change as decisions about long-term investments are developed.

Recommendations for those charged with decision making related to fossil fuels fall into four categories: holistically managing resources, designing for future conditions, taking a systems perspective, and expanding stakeholder interactions. These recommendations are not new, but are often set aside in the interest of short-term expediency. Thus, the most critical recommendation may be to recognize that these factors are becoming increasingly important to the success of long-term strategies related to fossil fuels.

3.02.9.1 Managing Resources Holistically

Resources need to be managed as closely connected systems in ways that recognize and address the connections between them. Integrated resource management, particularly with regard to water and energy, is becoming an increasingly common practice as the demand grows for both energy and water. Water utilities have long recognized the need to reduce energy consumption in their operations, and there is a growing understanding of the importance of water to electricity generators. Both communities are gaining an appreciation that saving water saves energy and saving energy saves water. DSM strategies in the electric sector not only reduce the need for additional peak generating capacity, but also help to conserve water needed for base load generation. Although water and energy issues are most commonly addressed by separate management, legal, and regulatory structures, there is increasing interaction across those structures as the impacts of climate and other environmental effects become more apparent. Such interactions need to become the norm.

3.02.9.2 Forward-Looking Design

The design of fossil energy infrastructure, from production through use, must be based upon expected environmental conditions of the next several decades, which may be considerably different from the past several decades. The expectation that energy infrastructure investments, including support infrastructure such as transportation, will operate over several decades illustrates the importance of designing for the envelope of plausible future conditions. Greater variability in temperature and precipitation, including extremes, and the potential for substantive changes to regional weather patterns, would represent a 'new normal' environment for infrastructure. Long-term drought and an increased frequency of severe weather and floods can each impact the production and use of fossil fuels. Decision makers must recognize the possibility of operating in these changed conditions, and develop designs, operating strategies, and financial plans that account for such changes.

3.02.9.3 Taking a Systems Perspective

Future development and use of fossil fuels must be understood as part of the broader, more complex energy, social, and economic system. The impacts of climate on fossil fuels illustrate the need to consider these energy resources in a broader systems context. The connections between energy and water, the interactions between renewable fuels and fossil fuels, and a growing awareness of the life cycle effects of energy production and use each illustrate the fact that it is no longer possible to isolate the economics, environmental effects, or the technological developments associated with fossil fuels from other energy resources or from socio-economic influences more generally. Although physical fossil fuel resources may not be impacted by climate, the ability to extract, process, and use them is impacted, often in ways that are not immediately apparent. For example, high temperatures could reduce yields of biofuel feedstock, leading to increased demand for, and price of, gasoline. While it has long been recognized that higher oil prices contribute to higher food prices, it is only recently been recognized that oil prices could be impacted by crop production.

The rate at which these changes are being made adds to the potential vulnerability of fossil energy resources. Rapid and extensive changes in technologies can lead to unforeseen problems (whether connected with the technology or not) that can create additional opposition to the changes. Recent examples include the increased application of hydraulic fracturing and the effort to evaluate geological carbon sequestration. In both cases, it is important to understand the broader systems context (technical, social, and economic) in which fossil fuels are developed and used.

3.02.9.4 Expanding Stakeholder Interactions

Substantive interactions with communities and other public stakeholder groups must be a basic component of fossil fuel development efforts. The need for organizations to interact with the public on the issue of development and use of fossil fuels has considerably increased with the growing understanding of the connection between fossil fuels and climate. Other issues, such as the impacts of coal mining, the concerns about the potential for hydraulic fracturing to impact water resources, and the Deepwater Horizon accident and spill, have raised the public visibility of the environmental impacts of fossil fuel production. These interactions need to go beyond providing technical and economic information, but need to acknowledge that public perceptions of technical issues are often strongly influenced by factors that are seemingly unrelated to the immediate issue. It is likely that dedicated expertise and resources will be needed to effectively respond to social perceptions and concerns that can have substantial influence on the ability to implement plans for developing or using fossil fuel resources.

Glossary

Atmospheric boundary layer The lowest part of the atmosphere where all of the meteorological phenomena that directly affect wind turbines are taking place.

Numerical Weather Prediction (NWP) Quantitative forecasts for all basic meteorological variables that fully characterize the weather, as produced by complex numerical models solving sets of differential equations on a three-dimensional spanning for a given region (and up to the whole globe) and the atmospheric boundary layer.

Reanalysis Based on all available meteorological observations at any given time, the reanalysis is an estimate of the state of the atmosphere at this time, as filtered through a dynamic model of the atmosphere (similar to those for producing NWPs).

Wind atlas Maps summarizing the assessment of the wind energy resource for any point over a region of interest. They may be produced based on linearized models, e.g., WAsP, or with more advanced approaches relying on some of the mesoscale models used for producing NWPs.

Wind power penetration Share of wind energy in the energy mix that allowed meeting the electrical demand for a country or a region, at a given time or over a period of time.

3.03.1 Introduction

Among the various forms of existing renewable energy sources, wind power has recently been the most successful, in terms of capacities deployed worldwide, but also in terms of its integration into existing power systems and electricity markets. Some of the historically leading countries in giving a prime importance to wind in their energy mix, that is, Denmark, Spain, and Germany, have reached significant levels of their electricity demand met by this renewable energy, either in absolute terms or relative to the electric demand itself, as quantified by the so-called wind power penetration. For instance in Denmark, wind energy generation allows fulfilling the overall needs in electricity of the whole country over a number of hours per year already, while it covers more than 20% of the electrical load on average over the last few years. Even though almost all wind turbines were installed onshore until the recent past, the trend today is to develop large-scale offshore wind farms (up to several GWs), owing to better wind conditions and space availability. Taking the example of Northern Europe (around the North Sea, Baltic Sea, and Irish Sea), most of future new wind farms are planned offshore, while the increase in onshore wind capacities is at least partly due to repowering, i.e., to the decommissioning of old turbines

http://dx.doi.org/10.1016/B978-0-12-384703-4.00310-5

and replacing them with newer more powerful ones. This justifies discussing wind energy in both the onshore and offshore cases, in view of the meteorological characteristics of the wind resource and of the technological aspects involved. A more lengthy discussion of the respective characteristics of onshore and offshore wind energy is available in EEA (2009), while a status report on the offshore wind energy developments was recently released (EWEA 2012).

At the end of 2010, 200 GW wind energy capacity was installed worldwide with an estimated generation of 410 TWh or 2% of the electricity consumption in the world (BTM 2011). The largest installed wind capacity in 2010 was first seen in China and second in the U.S.A. China doubled its wind nominal capacity in 2009, while installation in 2010 consumed a record of 19 GW. This corresponds to half of the whole wind turbine capacity added in the world that year and made China become the first country in the ranking of globally cumulative installed capacity. In terms of CO_2 emission, Europe's installed wind energy in 2011 generated 204 TWh or 6% of the electricity consumption of EU-27 countries and helped avoid emission of 133 million tonnes of CO_2 per year, equivalent to removing 30% of all cars in the EU off the roads (EWEA 2010).

Wind energy is available as the wind blows, as is commonly said. Since we cannot cover all basic aspects of wind energy here, let us provide some relevant starting points for the readers who may want to learn about these basics beforehand to focus on the issues relevant to wind energy and its climate vulnerability. First, an interactive introduction can be found online at windpower.org, while a solid overview of some of the key facts related to wind energy and its role in supplying electricity worldwide is gathered in a document produced by the European Wind Energy Association: *Wind Energy – The Facts* (EWEA 2009). Then, readers interested in a more detailed overview of these basics, also potentially requiring a sufficient scientific and technical background, are directed toward the manuscripts of Manwell et al. (2011) and Ackermann (2012).

The availability of wind energy at time scales of months to decades is, hence, seen as being mainly linked to trends in average wind speeds. In practice, things are slightly more complicated, since the possibility to optimally use wind energy is also linked to its variability and predictability at shorter time scales, in line with those characterizing our electricity consumption patterns and of those for the operation of the power. In addition, as can already be the case for a country with a very high wind power penetration like Denmark, wind farms may, for some time over the year, produce more energy than needed. Fortunately, Denmark has good transmission connections to its neighboring countries and the resource is normally not wasted at this time. Electricity can difficultly be stored today or be efficiently converted to other forms of energy. Finally, other climate parameters may be of importance, since, e.g., waves and sea ice may affect the accessibility of offshore wind farms, while local temperature fields may affect local thermal winds.

In order to discuss wind energy and its climate-related vulnerability, it is necessary to fully appraise the context and process of generating electricity from the wind. Some of these aspects are introduced and reviewed in the first stage below, by linking the wind resource itself and the electrical power generated from wind turbines or more generally wind farms. The challenges brought by the integration of wind energy into power systems and electricity markets are looked at, in the second stage, in order to fully describe the contextual aspects. Finally, in a third part, the sustainability and climate vulnerability of wind energy are discussed with focus on long-term trends in wind speeds, expected changes in its variability, issues related to icing and its consequences for wind turbine operations, as well as general aspects of extracting energy content from the atmosphere.

3.03.2 The Wind Resource and Related Electrical Power Generation

3.03.2.1 The Global Potential for Wind Energy

A first relevant issue is to figure out how much energy there is around and that could be extracted from the wind. This overall amount of energy is commonly referred to as global potential for wind energy. As an example analysis, Jacobsen (2009) reported that the globally-available wind power over land in locations worldwide with mean wind speeds exceeding 6.9 m/s at 80 m height is estimated to 72 TW (potentially generating 630–700 PWh/year). This resource would represent 5 times the world's total power production and 20 times the world's electric power production. Let us describe a bit more how one ends up with such potential.

In a comprehensive article, Miller et al. (2011) quite schematically break down the available wind resource, with the following reasoning. The Earth receives some 175.000 TW of radiation from the Sun. Of this, about 25% ends up heating the Earth. Since the Earth is round, the incoming radiation is not evenly heating up the surface. The uneven heat distribution leads to atmospheric pressure differences. Then again, only about 2% of that energy is converted into motion (Lorenz 1955), so that the total wind power content in the atmosphere is about 900 TW. About half of this is within the atmospheric boundary layer, which corresponds to the layer of the atmosphere where wind turbines are located. Assuming extraction, only onshore and near-shore (on the global scale) and excluding glaciers, a bit over 25% of the earth's land surface is available for the erection of turbines. Of the resulting 112 TW of power, about 68 TW can be converted to wind power when accounting for the Betz limit (to be discussed below when describing the conversion of wind into electric power). This would finally lead to approximately 596 PWh/year. This number does not exclude sites on grounds of their economic potential, where wind speeds would be too low to successfully place wind turbines. Since there are major uncertainties in this back-of-the-envelope estimate, it should be used as an indication of extractable wind power only. As there exists a number of feedback mechanisms between wide-spread wind power use and the atmospheric system, these mechanisms would require more investigation (which cannot be covered here), before a more realistic estimate can be obtained.

Going further than these simplified calculations, estimations of the global potential for wind energy may be refined by using the methodologies behind the production of wind atlases (see, e.g., windatlas.dk), i.e., with more focus the meteorological phenomena at the Earth's surface. For instance, the fourth assessment report from the International Panel on Climate Change reviewed the available literature and came up with a total technically exploitable potential for wind energy of 50 PWh/year. In the more pertinent Special Report on Renewable Energy Sources and Climate Change Mitigation (Wiser et al. 2011), a table of nine global assessments of global wind energy potential is shown, with different assumptions reaching potentials between 19.4 and 840 PWh/year. The high end is above the quick assessment of the total exploitable kinetic energy content of the atmospheric boundary layer (596 PWh/year), and therefore highly unlikely. For an overview and discussion of recent studies focusing on the global potential for wind energy, the interested readers are referred to Moriarty and Honnery (2011).

Even when using these more advanced approaches looking at relevant meteorological phenomena, these assessments of the global potential for wind energy are based on relatively coarse meteorological models with horizontal resolutions of tens of kilometers. Since terrain features are resolved at a distance of four to seven grid points only (Skamarock 2004), the practical horizontal resolutions of these models are certainly greater than 100 kilometers. Consequently, all the terrain effects that are known to increase wind speed, such as local speed-up effects over hills for instance, are ignored in these large-scale meteorological models. As a highly relevant practical example, Badger et al. (2010) showed that for a complex terrain site, the additional use of a microscale model like WAsP (www.wasp.dk) increases the mean wind power density for the best 50% of the area from 378 to 641 W/m^2. This means that for typical wind power sites, the resource is usually better than indicated by large-scale meteorological models. However, a caveat is that the higher resource is only valid for the best 10–30% of sites in a given area. Once the hill tops have been used for wind farms, the lower lying area is not as good anymore.

Overall, it is to be understood that even though the global potential for wind energy is fairly high, the uncertainty about its actual value, due to various considerations ranging from the impact of meteorological phenomena to the effect of the Earth surface itself, is also significant. Especially since a number of these influential factors are left substantially to chance along with climate evolution.

3.03.2.2 The Energy in the Wind and Its Harvesting through the Power Curve

The generation of energy from wind turbines originates from the weather and can, hence, be linked to some meteorological variables. This is the case for all common types of renewable energies: for hydro power, the energy content in a water reservoir is a function of rain and snow melt, while for solar energy, solar irradiance and cloud cover are some key meteorological variables.

The power output of a single wind turbine is a direct function of the strength of the wind over the rotor swept area. While wind speed is the meteorological variable of most relevance to power generation, air density (being a function of temperature, pressure, and humidity) also influences power output to a certain extent. This is since wind turbines convert the kinetic energy that is present in the wind into mechanical energy, consequently used for operating an electrical generator. Also, the wind over the rotor swept area varies with height, defining the so-called wind profile. The dependence on height is then linked to surface roughness, being different if offshore or onshore, and also a function of vegetation in the latter case. This dependence is also linked with atmospheric stability, roughly given by the vertical temperature gradient, accounting for the water surface temperature in the offshore case.

The process of the conversion of wind to electric power for a single turbine is described by the wind turbine power curve. Power curves roughly have the same shape no matter the manufacturer or turbine type. In mathematical terms, the underlying relationship between wind speed and power generation is explained by the cubic power law: the power available in the free flowing stream of wind is a cubic function of the wind speed. In parallel, owing to a number of factors like the Betz limit (or the more general limit derived by Okulov and Sørensen (2008)), the generator, and gearbox efficiencies as well as other losses, it is only possible to extract a certain percentage of the original power available in the wind.

In practice, a power curve has the characteristic form of example one depicted in Figure 1. The power production is

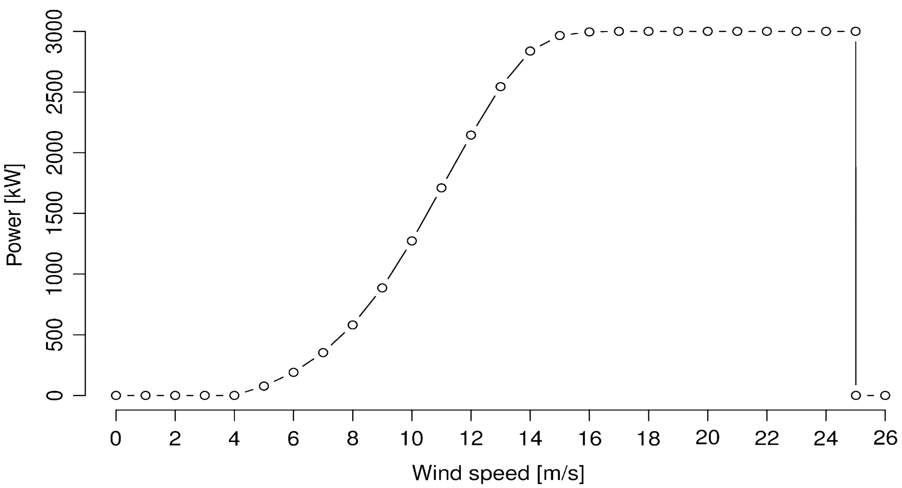

Figure 1 Example manufacturer power curve, for the Vestas V90 wind turbine with a nominal capacity of 3 MW (for an air density of 1.225 kg/m^3). Even though today, the nominal capacity of a wind turbine may be up to 5 MW, the characteristic shape of the power is still pretty much the same.

null below the cut-in wind speed, then sharply augments between the cut-in and rated wind speeds. At rated speed, it reaches nominal power, which is the power for which a turbine has been designed to operate. The nominal power serves as a reference value for denoting the capacity of a turbine and computing expected energy yields depending on site characteristics. The power production is close to being constant between the rated and cut-off wind speeds. At cut-off speed, the turbine stops for security reasons. This example of a power curve is for a fairly old wind turbine model from the 1990s. Various technological improvements have permitted lower cut-in and rated wind speed, while augmenting the cut-off speed.

It should be noted that these aspects of the conversion of the energy in the wind into electric power are of particular importance, since technological advances may indeed allow mitigating the potential effects of climate changes on our ability to harvest wind energy. For instance the changes in cut-in, rated and cut-off speeds will support energy extraction even if (very) low and high wind speeds were to become more frequent in the coming decades. Inversely, there will always be a steep part in such a power curve, which will amplify the magnitude of the fluctuations in the wind. The potential consequences of fluctuations of high magnitude will be discussed further below.

3.03.2.3 Spatial and Temporal Variability of the Wind Resource

Coarsely simplifying the meteorological aspects involved, winds originate from the movement of air masses from high to low pressure systems: the larger the difference in pressure, the stronger the resulting winds. This simple picture concerns the so-called geostrophic wind approximation for altitudes of, say, 1–2 km above ground level. Geostrophic winds can be seen as the free flows not affected by the Earth surface effects. Closer to the ground in the boundary layer, the winds' behavior becomes more complex due to natural obstacles, friction effects, the nature of the surface itself, temperature gradients, etc. As mentioned above, this potentially has the effect of increasing the density of wind power per unit surface area.

As a consequence, wind speed exhibits fluctuations over a wide range of frequencies. At the lowest end of the frequency range, variations in the order of days and over large geographical areas are induced by the movement of synoptic weather patterns, in more common terms by general changes in weather situations. In parallel, the fluctuations referred to as diurnal and semidiurnal cycles exist at a period of 12 and 24 h and for more localized areas, for instance at a coastline. They originate from thermal exchanges between the surface (land or sea) and the atmosphere, being weaker or stronger depending upon local climate, and also varying with seasons. For higher frequencies in the order of minutes to hours, more local effects potentially including the presence of cumulus clouds, convective cells, precipitation, or waves (for offshore sites) are the drivers for wind speed variations. Finally at higher frequencies (seconds to a few minutes, very small spatial scales), turbulence effects dominate. They are of less importance for the discussion here.

It was previously mentioned, that the lowest end of the frequency range corresponded to temporal scales in the order of days. This would be assuming that there is no variation at lower spatial and temporal scales, while it is actually the case. The effect of this interannual variability is, for instance, extensively treated by Pryor et al. (2006). As an illustrative example, the evolution of the yearly averaged wind speed (at 10 m above ground level) at the Schiphol airport near Amsterdam is shown in **Figure 2**, for the 55 years between 1950 and 2005. The average wind speed over that period is of 5.3 m/s, while the

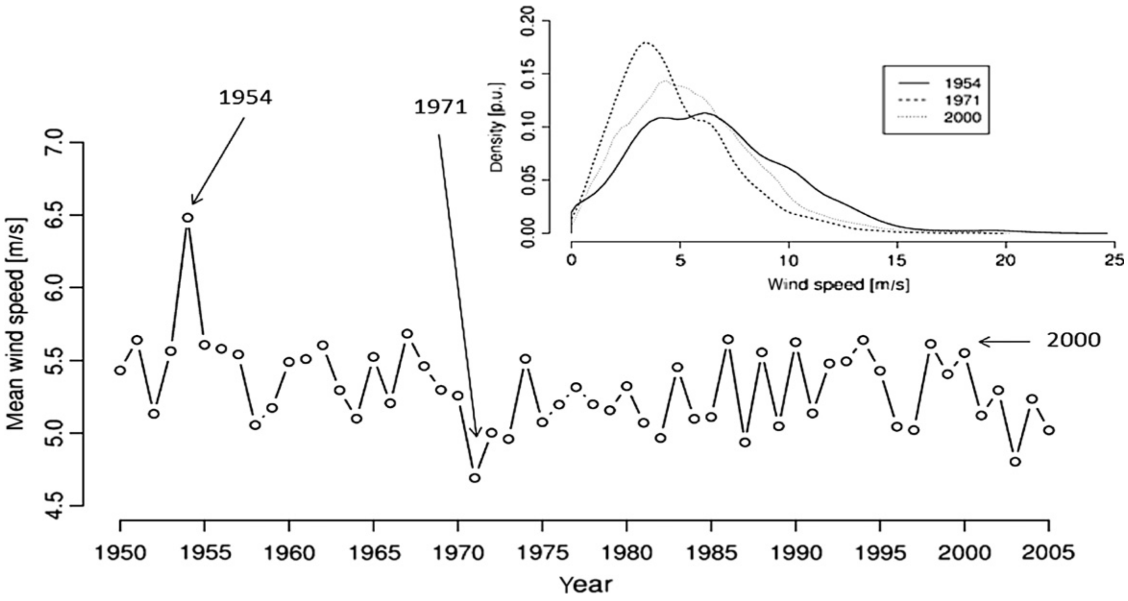

Figure 2 Evolution of the yearly mean wind speed at the Schiphol airport near Amsterdam, at 10 m above ground level. Wind measurements were taken from the KNMI-Hydra dataset (KNMI is the Royal Netherlands Meteorological Institute, which is duly acknowledged for making this dataset available). The average wind speed over that period is 5.3 m/s, while the variations from one year to the next are in the order of 0.5 m/s.

variations from one year to the next are in the order of 0.5 m/s. These variations may not appear that important (roughly only 10%). In practice, however, they will have a large impact on the distributions of wind speeds over the year (also shown in **Figure 2** for three example years), which are then amplified through the steep part of the power curve of wind turbines. Resulting changes in yearly energy throughput may be much greater due to the cubic effect of wind speed on power. In their discussion on the vulnerability of wind energy to climate, Schaeffer et al. (2012) insist on the fact that looking at trends in mean wind speed is clearly not sufficient, since a complete knowledge of wind speed distributions (and also of wind speed at various temporal and spatial frequencies) is necessary for appraising impacts on wind power generation.

To better explain and understand these very low frequency variations in wind speeds, Brayshaw et al. (2011) recently argued that they can be partly explained and predicted by large-scale climate patterns like the North Atlantic Oscillation (commonly abbreviated NAO). More generally, the linkage between wind characteristics and these large-scale climate patterns may be quite complicated, as indicated by a parallel study of Wang et al. (2011). Indeed, they uncovered that even though storminess (and hence wind speeds that would be close to wind turbine cut-offs) could somehow be related to the NAO, their relationship may be highly varying temporally and geographically. Overall, the crucial aspect to be remembered here is that characteristics of the wind relevant to power generation (e.g., mean wind speed, fluctuations, high winds) may be directly linked to some of the longer-term climate signals. This will be the particular focus of one of the further sections of this chapter.

3.03.2.4 Onshore and Offshore Specifics (Resource)

Generally, two major properties of the surface play a role for wind energy: the roughness of the landscape and the orography (i.e., terrain height variations). The wind speed is zero at ground level. With increasing altitude, it reaches the speeds given by the geostrophic winds above the boundary layer. Within the lowest layer, 80–150 m, the wind speed logarithmically rises with height, with a scaling parameter called the roughness. In high-roughness terrain, like cities or forests, the wind speed only slowly increases with height, while in low roughness terrain like grassland, sand, or sea, the wind speed quickly increases with height. For a good overview of wind power meteorology, see either Petersen et al. (1998a,b) or the WAsP help file (see www.wasp.dk). In the high-roughness areas, a few extra meters of tower for the wind turbine can pay off due to the higher energy in the wind higher up. While on grassland or offshore, the towers just have to keep the rotor high enough above ground as to not have too much wind shear (i.e., different speed) between the top and bottom of the rotor. Wind shear is a design parameter for the wind turbine and should not exceed a certain amount; otherwise, the lifetime of the turbine is going to suffer. Another feature of high roughness is the added turbulence, since small eddies are created at the terrain features.

While a different roughness in a wind resource calculation can change the result by rarely more than 20%, changes in orography or placement of the turbines on a hill can change the resource up to 70% due to the speed-up effect. On the top of a mountain the wind streamlines are compressed, and the Bernoulli effect keeping the mass flow constant increases the wind speed on top of the hill. However, the effect of mountains and hills is not limited to compression of the streamlines. At higher slopes, the wind can detach from the surface and start to come into large eddies behind the hill, in so-called recirculation zones. Those are very difficult to properly predict, and also with great computational effort, one cannot be sure to find the right result for the wind flow. However, as previously mentioned, in those areas, the wind resource is significantly enhanced in comparison to a coarser assessment, so in many cases, this is where wind power is built.

The situation is different offshore. For obvious reasons, orography does not play a role here, and the roughness is very low. This leads to a very low turbulence, high wind speed gradients with altitude, and generally higher wind energy. The lower turbulence also means lower variability, as the wind is generally not influenced by terrain variations for long fetches of ocean. In some cases, however, some special offshore weather types, such as open cellular convection, can increase the variability of offshore winds (Vincent 2011).

Wind turbines are usually arranged in wind farms, also called wind power plants due to the recent rise in size and possibilities to support the power system in critical times. Within those wind power plants, an optimization has to be done between the close spacing of turbines due to land availability, cabling cost or other needs, and the decreased wind resource due to wakes between the turbines. The wind turbine works by extracting kinetic energy from the wind, thereby slowing it down. A downstream turbine will therefore see less wind than one standing in the free stream. Onshore, this is taken care of by sufficient distance between the turbines, for example, five to seven rotor diameters. However, offshore in the reduced turbulence, the distances would have to be larger, as the wake structure can keep intact for a longer time. Satellite pictures have revealed that the wake (i.e., the area with reduced wind speed) behind the Danish offshore wind farm of Horns Rev can reach tens of kilometers (Christiansen 2007).

3.03.3 The Technological and Policy-Related Challenges for Wind Energy Integration

The global potential for wind energy may be seen as highly significant overall, while this available energy is well harvested through the conversion of wind to electric power. In parallel, our current understanding of space-time effects and onshore/offshore specifics was shown to be fairly good. It appears, however, that it is not only this core aspect of the resource that is of importance when considering the large-scale deployment of wind power and its potential climate vulnerability. Indeed, the context of the technological and policy-related challenges clearly contributes to the final use we make of the available wind energy. To push it to the extreme, some say (Inhaber (2011) for instance) that wind power cannot provide the benefits anticipated in terms of reductions of overall energy costs and CO_2 emissions. The reasons for such decrease in potential benefits from using wind energy mainly originate from the difficulty to integrate wind power generation into the existing power systems and electricity markets, especially when wind power penetration reaches substantial levels (say, more than 20–30% of the demand met over the year).

Some of the concepts of importance related to power systems operations and electricity markets are reviewed in the following, starting with the costs of wind energy and the policy framework. Then, we build on the question of the variability of the wind energy resource that was previously discussed by then looking at its predictability. Finally, we revisit the onshore and offshore specifics with focus on these technological and policy-related challenges.

3.03.3.1 The Cost of Wind Power

Even with a great resource, wind energy generation will only be used if eventually being an economically attractive form of energy. This is the reason why the economics of wind energy (for wind turbines connected to the power grid, that is, the vast bulk of installed wind turbines) is rapidly covered here. Some of the main parameters governing wind power economics include investment costs (also for foundation, grid-connection, etc.), operation and maintenance costs, turbine lifetime and discount rate, and finally the wind resource itself as discussed in the previous section. Of these, the most important parameters are the turbines' electricity production and their investment costs, while the parameters most affected by a potential climate evolution, are again the electricity generation from the turbines as well as the operations and maintenance costs.

As electricity production is highly dependent upon wind conditions, choosing the right turbine site is critical to achieving economic viability of the project. A major trend in recent years relates to the steady increase in the size of the turbines, being both larger and taller. Turbines are also more efficient in producing electricity, also making wind energy less vulnerable to low and very high wind conditions.

Some of the important costs related to wind energy and how they may be affected by climate-related aspects are viewed below. This potential impact of climate will most likely translate to increased costs of installing and operating wind farms.

3.03.3.1.1 Capital Costs

Capital costs of wind energy projects onshore are dominated by the price of the wind turbine itself (ex. works, i.e., the turbine as provided by the manufacturer and transported to the site). To give a rapid overview, Table 1 shows the cost structure for a medium sized turbine (850–1500 kW) sited on land and based on data selection from UK, Spain, Germany, and Denmark over 2001/2002. The turbine's share of total cost is typically a little less than 80%, but as shown in Table 1 considerable variations exist ranging from 74–82%. The single most important additional component is the cost of grid connection, which in some cases can account for almost half of balance-of-plant costs, followed by foundation, and cost of the electrical installation. Cost components such as consultancy and land normally account for only minor shares of balance-of-plant costs.

These costs may obviously differ if wind turbines are to be located in a certain country or another, though these variations are somewhat limited (Lemming et al. 2008). It appears overall, that these costs cannot be greatly impacted by climate-related aspects, since only the cost of land and road construction could be directly affected.

Table 1 Cost structure for a typically medium sized wind turbine (850–1500 kW), based on a limited data selection from Germany, Denmark, Spain, and UK for 2001/02. The cost structure tends to be fairly stable over time.

	Share of total cost (%)	*Typical share of other costs (%)*
Turbine (ex. works)	74–82	–
Foundation	1–6	20–25
Electric installation	1–9	10–15
Grid-connection	2–9	35–45
Consultancy	1–3	5–10
Land	1–3	5–10
Financial costs	1–5	5–10
Road construction	1–5	5–10

3.03.3.1.2 Operation and Maintenance Costs of Wind-Generated Power

Operation and maintenance (O&M) costs constitute a sizeable share of the total annual costs for a wind turbine. For a new turbine, these costs might easily reach an average share over the lifetime of the turbine of approximately 20–25% of total levelized cost per kWh produced. Therefore, O&M costs are attracting increasing attention, while manufacturers are attempting to lower these costs by developing new turbine designs requiring fewer regular service visits and less out-time of the turbines (higher availability). O&M costs are related to a limited number of cost components, which include regular maintenance (scheduled), repair (unscheduled), spare parts, insurance, and administration.

Based on existing experience from Germany, Spain, UK, and Denmark, O&M costs are, in general, estimated to be at a level of approximately 1.2–1.5 c€/kWh of produced wind power seen over the total lifetime of the turbines. Data from Spain indicate that a little less than 60% of this amount strictly goes to O&M of the turbine and the installations, the remaining 40% being almost equally split into insurance, rent of land (considered as part of O&M costs in Spain), and overhead.

Even though these O&M costs may appear quite limited today, these are the costs that may be the most impacted by climate for two reasons. The first is that turbines are subject to extreme winds and gusts; if they become more frequent, the number of failures and necessary unscheduled repairs would necessarily increase. The second is that accessibility to the wind farms would be reduced if more extreme weather conditions occurred, especially in the offshore case (high winds, waves, or sea ice).

3.03.3.1.3 The Cost of Energy Generated by Wind Power

The total cost per produced kWh (unit cost) is calculated by discounting and leveling investment and O&M costs over the lifetime of the turbine, divided by the annual electricity production. The unit cost of generation is thus calculated as an average cost over the turbine's lifetime. In reality, actual costs will be lower than the calculated average at the beginning of the turbine's life, due to low O&M costs, and will increase over the period of turbine use.

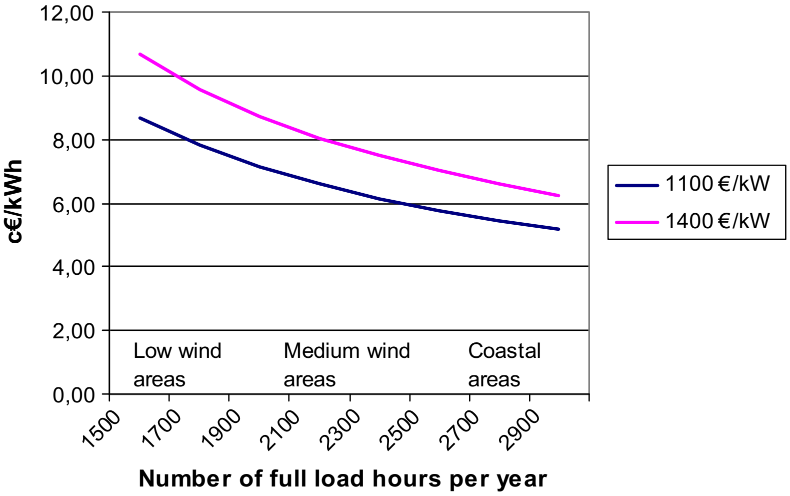

Figure 3 Calculated costs per kWh wind generated power as a function of the wind regime at the chosen site and two specific investment levels (number of full load hours).

The turbine's production of power is the single most important factor for the cost per generated unit of power. If a turbine is or is not sited at a good wind location, may totally determine if the turbine is profitable or runs with a loss. An example of the cost of wind produced energy is shown below based on the following assumptions:

- The calculations are performed for a land based medium sized turbine that is 850–1500 kW in size (a small turbine today).
- Investment costs equal 1100–1400 €/kW with an average of 1175 €/kW.
- Operation and maintenance costs are 1.45 c€/kWh in average over the lifetime of the turbine.
- The lifetime is set to 20 years.
- The discount rate is 7.5%.
- The economic analyses are carried out as socio-economic ones. No taxes, depreciation, risk premium, etc., are taken into account.

The calculated costs per kWh wind generated power as a function of the wind regime at the chosen sites are shown in Figure 3 below (In the figure, the number of full load hours is used to represent the wind regime. Full load hours are calculated as the turbine's average annual production divided by its rated power. The higher the number of full load hours, the higher the wind turbine's production at the chosen site). As shown, the cost ranges from approximately 7–10 c€/kWh at sites with low average wind speeds to approximately 5–6.5 c€/kWh at good coastal positions, with an average of approximately 7 c€/kWh at a medium wind site.

Approximately 75–80% of total power production costs for a wind turbine are related to capital costs, that is, costs for the turbine itself, foundation, electrical equipment, and grid-connection, etc. Thus, a wind turbine is so called capital intensive compared with conventional fossil fuel fired technologies as a natural gas power plant, where as much as 40–60% of total costs are related to fuel and operation and maintenance costs.

3.03.3.2 Policy Framework

Looking at the countries in, e.g., Europe that have installed significant amounts of wind energy in their electricity system, it is apparent that both the wind resource and the state of the technology are not in themselves the only determining factor. The growth of the wind energy sector in many countries is strongly affected by and responsive to the political frameworks, as well as a wide range of government policies. During the past two decades, a significant number of developed countries and, more recently, a growing number of developing nations have laid out renewable energy policy frameworks that have played a major role in the expansion of the wind energy market. These efforts have been motivated by the environmental benefits, climate change, security of supply, and economic development impacts of wind energy deployment, as well as the potential for reducing the cost of wind energy over time.

An early significant effort to deploy wind energy at a commercial scale occurred in California, with a combination of aggressive state and federal tax incentives spurring rapid growth in the 1980s. Nearly 2000 MW was installed until the California Public Utilities Commission suspended the market in 1985 (Bird et al. 2005). In the 1990s, wind energy deployment moved to Europe, with feed-in tariff policies initially established in Denmark and Germany, and later expanding to Spain and a number of other countries. A European study compared the support mechanisms that have been used and concluded that the most effective (ability to deliver an increase in renewable energy share in electricity delivered to consumers) and efficient (total support paid versus generation cost) support mechanism for onshore wind energy in Europe has been the feed-in tariff. In the U.S.A., the support mechanisms that have been used have been compared in a similar study (Bird et al. 2005) and the conclusion is that for the U.S.A., the renewable portfolio standards have shown to be the most effective support mechanism for wind energy.

Climate clearly has an impact on the resource itself. Our ability to harvest it and its potential cost may be counterbalanced by more proactive policies supporting further development and use of wind energy.

3.03.3.3 Power Systems Operation, Electricity Markets, and the Predictability Challenge

The management of an electric power grid is a difficult task, even when only the demand is variable and all power plant output can be scheduled, since production and demand should be strictly matched at all times. As previously explained, wind energy generation cannot be scheduled while being highly variable. This has the consequence of making the power grid even more difficult to manage, while potentially increasing the various costs involved. Another consequence is that at large levels of wind power penetration, this constant-matching constraint may lead to spilling of wind energy when very large quantities of wind energy are produced when not needed.

While the final operation of the power grid is that task of the grid operator, optimal schedules and dispatch are increasingly determined based on electricity markets, where the various demand and production offers are accordingly gathered and matched. A core characteristic of these electricity markets is that all offers should be submitted a certain time in advance, from a few minutes to more than a day.

Consequently, in view of the time scales relevant for the operation of power systems and electricity markets and given the variability of wind energy generation, it is necessary to predict what wind power production may be in the near future. Forecasting of wind power generation is currently seen as a challenge, at least at levels of accuracy required by the users of such forecasts. It has consequently attracted the attention of a large number of researchers and practitioners, spanning a wide range of potential paths for forecast improvements.

These time scales of interest range between a few minutes to several days ahead. The shorter lead times correspond to the needs of the grid operator (often referred to as Independent System Operator, ISO, or Transmission System Operator, TSO) in order to optimally operate reserves for the continuous balance of the power system. They also serve as input to wind farm controllers (most importantly for large wind farms situated offshore). These short-lead times are also relevant for market participation in countries like the Australia, New Zealand, and U.S.A. In contrast, in the European context of power systems operations and market participation, the lead time of interest are up to two days ahead since commitment and dispatch are based on a day-ahead market.

In an operational context, prediction systems use past and real-time power and meteorological observations as input, as well as current weather forecasts provided by National weather offices or alternatively by commercial forecast providers. The latter permit one to capture the trend in the evolution of weather systems, and these may affect relevant meteorological variables at the level of the wind farm (or portfolio) of interest. In parallel, the observations permit one to fully appraise the current situation at the level of the wind farm and to take advantage of the inertia in the evolution of weather systems to better predict its evolution in the short term.

A potential issue with these wind power forecasts relates to their level of accuracy. Their quality may indeed be highly variable and characterized by a wide range of factors. The lead time of the forecast is obviously one key factor, as one naturally expects forecasts to be less accurate as the lead time gets further in the future due to the inherently chaotic behavior of the atmosphere. Also, the quality of the forecast highly depends upon the local wind climate and local terrain where wind farms are located; it is easier to predict wind power generation in the North of Denmark than on the steep hills of the South Pyrenees in Spain. Finally, forecast accuracy is also highly dependant upon the forecast provider and the method he uses.

The lack of predictability of future wind power generation is commonly seen as a threat to the reliable and economic integration of this renewable energy in current power systems. Various studies have shown, however, that the progress in predicting such power output has been tremendous over the last decade. As a representative example, Ernst et al. (2007) showed that the level of root mean square error for wind power predictions over all of Germany decreased by 1/3 between 2001 and 2006. More improvements are expected in the near future owing to the increased commitment of the meteorological community for upgrading the current forecast systems for relevant meteorological variables.

A reason why we mention the challenge of predictability is that we are not sure of the predictability of relevant meteorological variables into the future. Some very preliminary works have actually been looking at whether or not it is possible to predict wind power generation for the next season, based on some seasonal forecasts of climate indicators (Brayshaw et al. 2011). Direct approaches based on statistical considerations may already permit one to predict the average energy generation for the coming month (García-Bustamante et al. 2009).

3.03.3.4 Onshore and Offshore Specifics (Technology and Integration)

Compared to land-based turbines, the cost structure of offshore wind farms are mainly related to the three following issues. First, foundations are considerably more costly for offshore turbines. The costs depend on both the sea depth and the chosen principle of construction. For a conventional turbine sited on land, the share of the total cost for the foundation is normally approximately four to six percent. In contrast, for the first two large offshore projects in the world, Horns and Nysted in Denmark, the foundations accounted for 21% of the total investment. Second, the cost of the grid connection, i.e., the transformer station and the transmission cable to land, may be much higher for offshore wind farms. The connections between the turbines and to the centrally located transformer station are buried in the sea bed and generate additional costs compared with on-land sites. Again, for these two large offshore projects at Horns Rev and Nysted, the average cost for the transformer station and main transmission cable represents 16%, while the so-called array cables connecting the turbines with the transformer station account for 5% of the total project investment. Finally as a third point, access to an offshore wind farm is often by boat or in some cases by helicopter. This is considerably more difficult and expensive than for a land-based turbine and the cost of operation and maintenance (O&M, the most influenced by climate parameters) is typically 30–40% higher than for land-based wind farms. As an illustrative example, Nielsen et al. (2010) analyzed the main differences between Danish land-based and offshore projects, also including a projection until 2050. Overall, it was concluded that the cost of electricity today is approximately 40% higher from an offshore wind farm than from a land-based wind farm. This difference is expected to lower to 25% by 2050.

In parallel, regarding the integration of the electricity generated, a specificity of offshore wind power is that offshore wind farms concentrate very large capacities at a single location or over a fairly small area. It is common today to talk of future offshore wind farms with nominal capacities in GWs. Onshore, the same level of installed capacity is usually spread over an area of significant size, which yields a smoothing of power fluctuations (Giebel 2007). Since this smoothing is hardly present offshore, the magnitude of power fluctuations may reach very significant levels and require more flexible generation units connected to the grid in order to mitigate these large fluctuations. A discussion on these aspects is available in Sørensen et al. (2009). This finally translates to additional costs for the management of the power system to be put into perspective with the larger quantities of wind energy that can be harvested offshore.

3.03.4 Climate and Wind Energy

Some of the crucial climate parameters for wind energy were discussed in Section 3.10.1 Introduction. By far, the most important of these parameters is the wind in the lowest part of the atmosphere. Local winds depend on the surface characteristics: terrain, type of surface, and nearby obstacles and are always superimposed upon the larger scale wind systems. When larger scale winds are light, local winds, e.g., sea breezes may dominate the wind pattern at the location of a wind turbine. Thus, changes in global, regional, or local temperature fields in local vegetation and in other factors will affect the wind climate. Note, however, that other climate parameters may also be of importance, as for instance icing has a noticeable impact on wind energy production. Overall, emphasis is placed here on some of the ways wind energy technology and the electricity production may be affected by climate, owing to changes in (i) the wind resource, (ii) extreme wind speeds (50-year wind), (iii) occurrence of atmospheric icing, and (iv) occurrence of sea ice (especially relevant for offshore applications).

A network of more than 60 researchers from Nordic countries worked between 2003 and 2010 on assessing the impact of climate on all renewable energy sources in the five Nordic countries. The work was structured into two large projects: Climate and Energy (2003–06) and Climate and Energy Systems (2007–10) http://en.vedur.is/ces, financially supported by the Nordic Council of Ministers and the Nordic energy industry. All renewable energy sources of importance for electricity generation were studied, i.e., hydro power, wind, solar, and biomass. The basis for quantifying the climate impact was a comprehensive study of a large number of scenarios generated by global and regional climate models. The main results from the two projects with regard to wind energy were reported in Clausen et al. (2007) and Clausen et al. (2012), while substantially inspiring the discussion in the present section. A top-down approach was followed there, the conclusions of which may be affected by the limited predictability of relevant climate variables at these time scales at a regional level.

3.03.4.1 Wind Resource

Wind speed in relation with climate has attracted increasing attention over the last years, especially in relation with the issue of generating wind energy. Focusing on wind speeds is quite new – most efforts were originally focused on the temperature variable.

Certain studies mention a global trend of increasing values in wind speed, like the recent one of Young et al. (2011) focusing on oceanic wind speeds based on a 23-year database of calibrated and validated satellite altimeter measurements, or that of Troccoli et al. (2012) concentrating on the Australian case. In contrast, other works observe that terrestrial wind speeds have slowed down over the last decades (McVicar and Roderick 2010). Overall, review articles analyzing these various studies conclude on a cautious note, such that it may actually be difficult to formulate solid conclusions on future average wind speeds over the coming decades (Pryor and Barthelmie 2010), especially if considering the question of wind speed at various heights relevant for wind energy generation. This is owing to the complex mechanisms involved in the evolution of climate variables, not only affecting average wind speeds close to the surface but also parameters that may affect wind profiles (i.e., the way that wind speed evolve depending upon height). For instance in response to the work of McVicar and Roderick (2010) and Vautard et al. (2010) explained that the stilling in observed wind speeds could be partly explained by changes in surface roughness (for 10–25%), linked with biomass and land-use change in Eurasia. In parallel, changes in atmospheric circulation, as captured from the ERA-Interim reanalysis data, could explain between 10 and 50% of this observed decrease in wind speeds. **Figure 4** gives an illustration of the main results from that study, showing the trends in wind speeds observed at meteorological stations worldwide and from the ECMWF ERA-Interim reanalysis. For more information on this reanalysis, which is widely used as input to climate studies, the reader is referred to Dee et al. (2011).

3.03.4.2 Extreme and Strong Winds

The extreme wind U_{50} is the 10-min average wind speed with a return period of 50 years and is an important design parameter for wind turbines, while strong winds are more important for the operation and maintenance of especially offshore wind farms. Most offshore wind farms are accessed by boat. Before a visit to an offshore wind farm, the operation and maintenance planner looks for so-called weather windows where the wind and wave spectra allows access to the wind farm twice: first to place the maintenance crew and their tools at the wind turbines and second to pick them up after the work is finished. The number of days per year where the wind farm can be accessed is used during the planning period where the developer will compare potential wind farm sites and different means to access the wind farm; second, in the daily planning of maintenance, strong winds

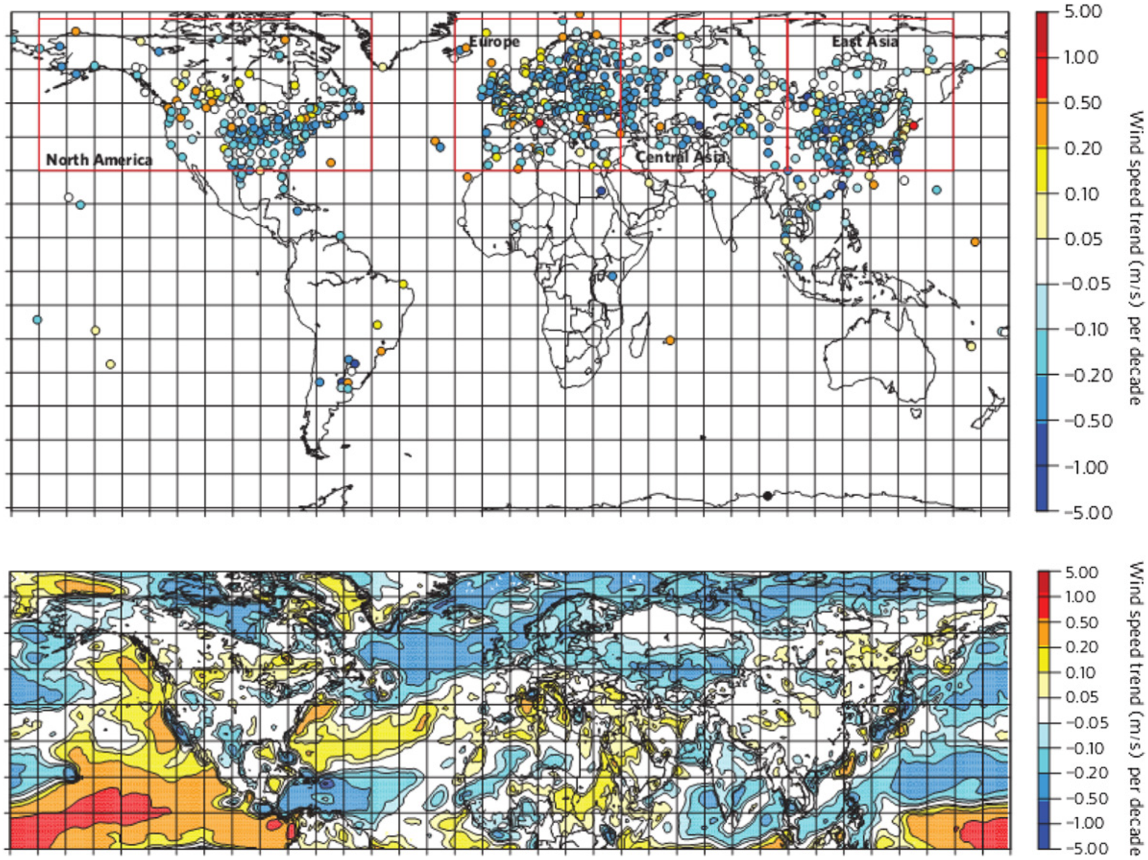

Figure 4 Observed and reanalysis surface wind speed trends (taken from Vautard et al. 2010). Top: linear trends in the observed wind speeds at selected meteorological stations (822 worldwide) in m/s per decade, over the period 1979–2008. Bottom: linear trends from the ECMWF ERA-interim reanalyses, calculated using mean daily 10 m wind speed values over the period 1989–2009. Reproduced from Vautard, R., J. Cattiaux, P. Yiou, J.-N. Thépaut, and P. Ciais, 2010: Northern hemisphere atmospheric stilling partly attributed to an increase in surface roughness. *Nat. Geosci.*, **3,** 756–761.

influence decision-making concerning ship travel to the wind farm. In this respect, strong winds are important as they occur much more frequently than extreme winds (e.g., wind speeds >17 m/s occur 3–4 days per year at 10 m height in the Fehmern Belt between Denmark and Germany).

Studies about the effect of climate variability on strong and extreme winds are rare while mainly following a top-down approach. They were recently reviewed by Pryor and Barthelmie (2010). As shown in Figure 2, changes in yearly average wind speeds translate to potentially substantially different distributions of wind speeds over the year. Intuitively, higher average wind speeds yield more frequent strong wind speeds and larger probabilities of observing extreme wind speeds. Therefore, even if higher mean wind speeds may be seen as beneficial, allowing more energy to be produced from the wind over the year, this may not be realized in practice due to the potentially negative effects of strong and extreme winds, for instance, those related to cut-off events, turbines failures, and access problems for offshore wind farms.

In contrast to this top-down approach based on climate models permitting projections to be made regarding future extreme wind speeds, a bottom-up strategy evaluates which increase in extreme speeds (magnitude and frequency) may be tolerated by current technology while not leading to additional challenges in terms of offshore wind farm accessibility.

3.03.4.3 Icing

With the development of new wind projects in the Northern part of Scandinavia, Canada, Austria, and Switzerland, a new market segment for wind power has emerged: wind power in a cold climate. The market conditions here can be divided in two sub-groups: areas with occurrence of low temperatures and areas where icing will occur. The main effect of icing is decreased aerodynamic performance and potentially excess loads triggered by unevenly distributed ice on the blades. Both lead to a loss in energy production and affect the economics of wind turbines. There might also be health and safety effects associated with operation of wind turbines in areas with icing due to a risk of ice throw (for a reference work on that topic see Biswas et al. (2012)). Sites prone to atmospheric icing are typically located at northern latitudes or at high altitudes, such as mountain ridges that provide favorable wind conditions. Operation of wind turbines in dry areas with low ambient temperatures (below −20 °C) and a low risk of icing, is often a matter of selection of the right steel quality for the wind turbine, installing (e.g., heating in the gearbox) the hydraulic system, and in other critical components in order to facilitate cold start.

Moisture is also an important factor, since increased moisture facilitates icing. Hence, potential evolutions of average moisture levels in the coming decades may affect wind energy.

For instance, even with the projected increasing winter temperatures of more than 2 °C in northern Scandinavia (Kjellström et al. 2012) leading to a trend with fewer icing days, the parallel trend of increased wintertime precipitation and cloud cover (Clausen et al. 2007) may well lead to more frequent icing overall. On the other hand, it is possible that during a transient change these combined weather conditions could undergo a nonlinear change so that the conditions throughout the century may not just be simple scaling or interpolation between present and end-of-century conditions. A more in-depth analysis of freezing point crossover under humid conditions is necessary to provide reliable information about whether these competing mechanisms will result in a temporary increase or decrease of icing conditions as temperatures are on the rise. Note that technological developments will most certainly help making wind turbines less vulnerable to icing.

3.03.4.4 Sea Ice

Let us consider the example of the Baltic Sea, where a number of offshore wind farms are planned, which annually freezes nowadays. The maximum annual ice extent occurs between January and March, when ice covers 52 000–420 000 km^2 and on the average 218 000 km^2. At the latitude of Stockholm, the ice probability is 50%. The ice season lasts from weeks in the south to seven months in the north. The thickness of the ice varies between 50–70 cm during normal winters and 80–110 cm during colder winters. In the coastal areas of the Gulf of Bothnia South and the Gulf of Finland, icing periods last on average for 100–150 days. In the south of Stockholm, the icing period is on average less than 60 days. In the sea areas around Denmark and the West/South coast of Sweden, the icing period is less than 30 days on average.

For wind turbine foundations, the most critical issue is the thickness of drifting sea ice. In coastal regions, limited ice action is exerted against the foundations, as the ice becomes anchored on the shoreline, rocks, shallows, and islands. In early winter ice movements are by thin ice only, while during late spring the ice becomes soft and deteriorated and movements by thick ice is seen. In the northern part of the Baltic Sea, drifting ice can be 0.8 m thick with significant piling of ice. During winter, loads on structures are from thermal ice expansion only. After a storm, ice flows that have broken off can move about, causing loading on structures. The larger the solid ice field, the larger the loads. The greatest loads are usually experienced in springtime, when ice starts moving and piling. In the northern part of the Baltic Sea, the pile up against the tower and foundation can reach a height of 10 m and may damage tower structures.

In terms of climate vulnerability, even though sea ice is certainly problematic for offshore turbines foundations as well as for operations and maintenance of offshore wind farms, climate is assumed to not affect wind energy owing to increased sea ice in the coming decades.

3.03.5 Conclusions

The energy generation from wind turbines is highly sensitive to a number of climate parameters, either directly (wind speed at least) or indirectly (wave, sea ice, etc.). Making projections regarding the climate vulnerability of wind energy is a difficult task. This is because these parameters have attracted less attention from the climate research community than temperature, which was seen as the lead variable when studying climate change. Their potential evolution with a drift in existing climate is then less well understood.

Various studies have looked at trends in wind speeds either globally or at the level of specific countries, with contrasting results and that was potentially inconclusive overall. What comes out of these studies is that instead of only focusing on mean wind speeds and at a particular height (say, 10 m above ground level), it is of crucial importance to appraise the evolution of the complete distributions of wind speeds, not only the mean and at various heights, hence, fully describing the potential wind conditions and wind profiles that the turbines may experience.

In parallel to the wind itself, waves, icing, and sea ice are identified as the main parameters that may indirectly affect wind energy. Icing is relevant to both onshore and offshore cases, while obviously sea ice and waves are only relevant for the latter case. It is difficult to foresee evolutions in wave characteristics – the reason why this was not extensively treated here. Winds and waves are directly related offshore and should be jointly examined. Regarding icing and sea ice, a climate evolution with increasing average regional and local temperatures might smoothly dampen their undesirable effects on wind energy production.

Globally, the climate vulnerability of wind energy is to be put into perspective with the technological and policy-related framework. The technology of wind turbines is evolving and making them less sensitive to very low and very high winds. Technological changes and cycles of decommissioning and decommissioning of wind turbines are faster than climate evolution, allowing for an adaptation of our approach to optimally harvesting energy from the wind. Also, changes in the ways energy mix or the way energy is transported, distributed, and consumed, may help mitigate the effect of enhanced variability and lack of predictability of wind conditions. It is somehow our role to adapt to the specifics of using this form of energy production and to its potential change in characteristics over the coming decades and centuries.

Glossary

AOGCMs Atmosphere–Ocean General Circulation Models.

IEA International Energy Authority.

kWh is a kilowatt hour which is equivalent to 3.6 MJ (i.e., one million (10^6) joules) of energy.

RCMs Regional Climate Models.

SRES Special Report on Emission Scenarios. The SRES scenarios were constructed to characterize possible future emissions of greenhouse gases and aerosol precursor emissions. Examples of these scenarios as used herein are A2, A1B, B1, which are ordered in descending order in terms of the amount of climate forcing (A2 being the highest and B1 the lowest).

Storm tracks indicate preferred regions of extra-tropical cyclone activity.

Technical potential resource accounts for geographical constraints to harnessing the resource and losses in the energy conversion.

Theoretical potential resource is an estimate of the total energy in the fluid.

3.04.1 Introduction and Objectives of This Chapter

According to the International Energy Authority (IEA) global energy use is projected to increase by 1.5% per annum between 2007 and 2030 (International Energy Agency 2011). This projected increase in demand coupled with concerns regarding the current reliance on fossil-fuels and the associated geopolitical and environmental concerns has led to increased interest in harnessing renewable energy sources. Again according to scenarios developed by the IEA, use of non-hydro renewable energy technologies (including wind, solar, tidal, wave, and bio-energy) is likely to see marked increases in global penetration particularly of the power generation mix, rising from 2.5% in 2007 to 8.6% in 2030, with wind power showing the greatest absolute increase in market share (International Energy Agency 2011).

Available energy from the seas and the air above them greatly exceeds current total human energy usage (Edenhofer et al. 2012). However, harnessing that energy presents a number of technological challenges and virtually all of the energy resources exhibit some form of dependence on the global climate system. Thus we address the following questions:

1. What is the estimated resource for wind, wave, tidal, or sea currents, and what is the current status of technology deployment to harness those resources?

2. How susceptible are those resources to climate change? That is, what impact might global climate change, including changes in the frequency and/or intensity of extreme events, have on wind, wave, tidal, or sea currents, the magnitude of the resources, or our ability to harness those resources?

Further, where possible, we indicate what actions (adaptation/mitigation) might be undertaken to minimize/eliminate the negative consequences of large-scale implementation of these technologies and/or potential impacts of climate change or to take advantage of the opportunities provided thereby.

3.04.2 Resource Estimates and Status of Deployment

A synthesis for all renewable technologies as developed by the IEA is given in Table 1; other estimates are available from the recently released Intergovernmental Panel on Climate Change (IPCC) report on renewable energy sources (Edenhofer et al. 2012). Specific resource estimates for the ocean energy technologies described herein are given below. Key challenges to making these types of resource estimates for any renewable source are as follows:

- The resource potential is not fixed, but rather is a function of the technology available, economics and assumptions regarding constraints to developing the resource.
- Potential resources can be computed on the basis of a range of different assumptions. The theoretical potential resource is an estimate of the total energy in the fluid under consideration, while the technical potential resource accounts for geographical constraints to harnessing the resource and losses in the energy conversion (Hoogwijk et al. 2004). Thus the former will exceed the latter.

In part because of the challenges articulated above, resource estimates exhibit large variability from analysis to analysis (Edenhofer et al. 2012). Nevertheless, prior analyses have indicated that the marine energy sources could make a substantial contribution toward electricity supply in many countries (del Rio 2011). For example, one analysis of the UK wave and tidal resources indicated realistic target contributions to electricity supply of 75 TWh year^{-1} (Kerr 2005), which equates to approximately one-quarter of the current demand in the United Kingdom (UK Department of Energy and Climate Change 2010), and approximately 20% of Denmark's electricity supply already derives from wind power plants, with about one-third from offshore installations.

Table 1 Total global realizable resource potentials for renewable technologies in the medium term (i.e., by the 2020s) (International Energy Agency 2008)

Technology	*Resource (in TWh)*
Biogas	644
Solid biomass	1841
Municipal waste	258
Geothermal electricity	87
Hydropower	4041
Solar photovoltaic	394
Solar thermal electricity	91
Tidal and wave energy	156
Onshore wind	962
Offshore wind	443

Data from International Energy Agency, 2008: *Deploying Renewables: Principles for Effective Policies*, OECD/IEA. [Available online from http://www.iea.org/publications/free_ new_Desc.asp?PUBS_ID=2046.]

Despite earlier progress on other technologies that rely upon harnessing energy from thermal or salient gradients (Duguay 1977) and the development of some demonstration projects (Vega 2003), the primary mechanisms for harnessing ocean renewable energy considered here involve deployment of devices to convert the kinetic energy in wind, wave, tidal, or sea currents into electrical power (Barthelmie et al. 2000; Bedard et al. 2010). A fairly recent review of US projects in all the water power technologies is given in a recent report from the U.S. Department of Energy (U.S. Department of Energy: Office of Energy Efficiency and Renewable Energy 2009).

3.04.2.1 Wind Energy

3.04.2.1.1 Harnessing the Power of the Wind

The potential harnessable power in the wind at any moment is given by

$$E = \frac{1}{2}\rho U^3 \qquad [1]$$

where

E is the energy density

ρ is the air density

U is the wind speed at hub-height

The actual electrical power production from a wind turbine is a nonlinear function of the incident wind speed and is described using a turbine specific 'power curve.' A turbine power curve describes the relationship between hub-height wind speed and electrical power produced. At low wind speeds below 'cut-in,' no electrical power is produced. Power production increases rapidly as wind speeds exceed the cut-in (which is typically approximately 4 m s^{-1}), to achieve rated power (the rated capacity of the wind turbine) at wind speeds of approximately 15 m s^{-1}. A further increase of the wind speed does not increase the electrical power production and at excess wind speeds (typically above approximately 25 m s^{-1}) electrical power production ceases (although this condition is realized only very infrequently at currently operating wind power plants). Thus actual power production from wind turbines is dominated by the upper percentiles of the wind speed probability distribution. For a typical high-wind speed site suitable for wind energy development up to 90% of the electricity is produced by the highest 50% of wind speeds and one-quarter of electricity generated derives from the highest 10% of wind speeds (Pryor and Barthelmie 2010).

Wind turbines convert the kinetic energy in the atmospheric flow into mechanical energy typically by harnessing the rotation of aerodynamically blades into faster-rotating gears. While a number of designs have been tested, most commercial machines use three blades arranged on a horizontal axis wind turbine wherein as the wind passes over the blades, lift is created causing the rotor to turn. This mechanical energy is then converted into electricity using a generator (Barthelmie et al. 2000; Manwell et al. 2002). The maximum power that may be extracted by a wind or tidal current turbine is approximately 59%. At this aerodynamic efficiency, the wind speed directly behind the wind turbine is approximately one-third of the incident wind speed at hub-height (DNV/Risø 2002).

3.04.2.1.2 Resource Magnitude

There are a range of estimates of the global wind energy resource magnitude, but the current technical potential resource was estimated to be 840 PWh year^{-1} even when only offshore regions with water depths >200 m were excluded, and a capacity factor of 20% was applied (Lu et al. 2009). This exceeds current worldwide consumption of electricity by 40-fold (Lu et al. 2009). Even if lower estimates of 110 PWh year^{-1} (Krewitt et al. 2009) prove more accurate, the total resource is substantial.

Wind speeds offshore are typically of greater magnitude and more persistent than at geographically proximal land sites leading to higher capacity factors (i.e., ratio of actual output from a power plant over a period of time to the potential output if it had operated at full rated capacity for the entire period) at offshore locations (Pryor and Barthelmie 2001). Thus even confining analyses to the near shore region, a substantial fraction of both the theoretical and technically feasible resources, lie offshore (Lu et al. 2009) (Table 1).

3.04.2.1.3 Current Status of Wind Energy Deployment

Installed wind energy capacity rose from approximately 94 GW in 2007 (Milford 2008) to nearly 121 GW in 2008 (News 2009), and over 197 GW by the end of 2010 (Global Wind Energy Council 2011). It has been suggested that installed capacity may equal 400 GW by 2014 (Global Wind Energy Council 2011), and exceed 700 GW by 2017 (de Vries 2008).

Europe is currently the global leader in offshore wind installations with nearly 1.5 GW installed in European waters in 2008 (de Vries 2009) (Table 2), and during 2010 of the nearly 9.3 GW of wind energy installed in the EU-27 during 2010, almost 1 GW was installed offshore (Global Wind Energy Council 2011). In one global analysis conducted by the IEA, electricity generation from wind power (including offshore wind plants) is projected to reach 4.5% of total global generation in 2030 compared to less than 1% in 2007 (International Energy Agency 2011).

Table 2 National offshore wind energy capacity within the European Union in 2008 and estimated national projections for 2020 (Green and Vasilakos 2011)

Country	*2008 Capacity (GW)*	*2020 National plan (GW)*
United Kingdom	0.59	13
Germany	0.01	10
France	–	6
Netherlands	0.25	5.18
Sweden	0.13	1.82
Denmark	0.41	1.34
Belgium	0.03	1.8
Spain	–	3
Finland	0.02	–
Ireland	0.03	0.6
Italy	–	0.7
Poland	–	0.5
Greece	–	0.3
Estonia	–	0
Latvia	–	0
Lithuania	–	0
Others	–	1
EU-27	1.47	45.2

Data from Green, R., and N. Vasilakos, 2011: The economics of offshore wind. *Energy Policy*, **39**, 496–502.

The European Union market for onshore wind energy grew by an average 32% per year from 1992 to 2004 (European Wind Energy Association 2009b) and has continued to experience sustained investment (Figure 1). In order to achieve either the European Union (EU) goal of 20% of energy from renewable by 2020 or the European Wind Energy Association (EWEA) target of 40 GW of offshore wind in the EU by 2020, similar expansion of the exploitation of vast offshore wind resources will be required. Assuming this level of growth, cumulative offshore installed wind capacity in Europe may reach 40 GW by 2020 and 150 GW in 2030 (de Vries 2009) (Table 2). Although in the near-term, the United Kingdom and Germany will likely to continue to make the greatest investments in offshore installations (Figure 2 and Table 2), other countries are also increasingly seeking to develop offshore wind power plants (de Vries 2009), and the first offshore wind farm in China began generation in the summer of 2010 (Global Wind Energy Council 2011).

Virtually all wind turbines that have been installed offshore to date have been deployed in relatively shallow waters (<20 m) and use either monopole, tripod, or gravity base foundations (Abbatt and Molina 1993; Dabberdt et al. 1993; DNV/Risø 2002; European Wind Energy Association 2009a). Much of the offshore wind resource lies in deep waters where hydrodynamic loads will likely be higher and floating support platforms may be the optimal support structure (European Wind Energy Association 2009a; Henderson 2009; Jonkman 2009).

3.04.2.2 Wave Energy

3.04.2.2.1 Harnessing the Power of Waves

Water waves observed in the field are the result of combined mechanics of wave generation, dissipation, propagation, and nonlinear wave–wave interactions. The primary generation mechanism is friction from the overlying atmosphere and thus the state of the sea is related to the in situ atmospheric conditions. However, the coupling is complex and bidirectional. The growth rate of waves is proportional to the square of the friction velocity (which is a metric of momentum dissipation at the surface), and there is a reciprocal coupling to the atmosphere, where the roughness of the water surface (which is a function of the wave field) is a key determinant of the near surface wind speeds and the shape of the vertical profile of winds (Peña and Gryning 2008). The actual wave field is not solely a function of local production and dissipation but also includes a component from remotely generated swells (long-wavelength waves generated by distant atmospheric phenomena) (Smedman et al. 1999).

As discussed further below, wave climates are important not only to the wave energy resource, but also fatigue and extreme loading on offshore structures such as wind turbines. Under some simplifying assumptions, and in moderate water depths,

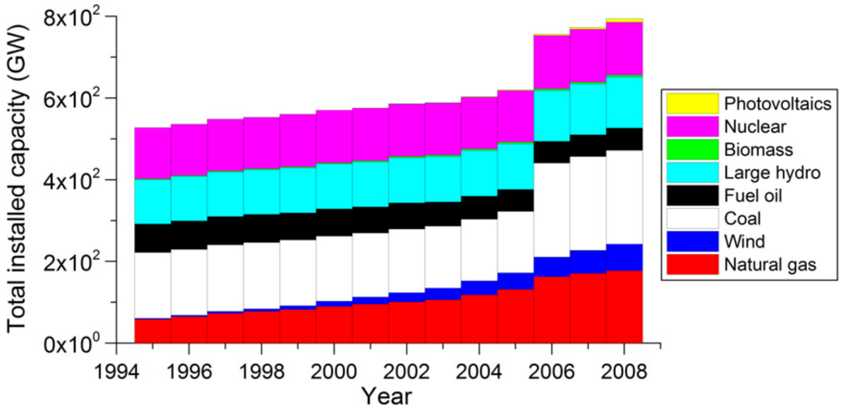

Figure 1 Total installed capacity (GW) in the European Union 1995–2008. Prior to May 2005, the data reflect the EU-15, prior to January 2007 it is the EU-25 and subsequent to that the data are drawn from the EU-27. Data taken from European Wind Energy Association E, 2009c: Pure power: wind energy targets for 2020 and 2030, EWEA. [Available online at http://www.ewea.org/fileadmin/ewea_documents/documents/publications/reports/Pure_Power_Full_Report.pdf.]

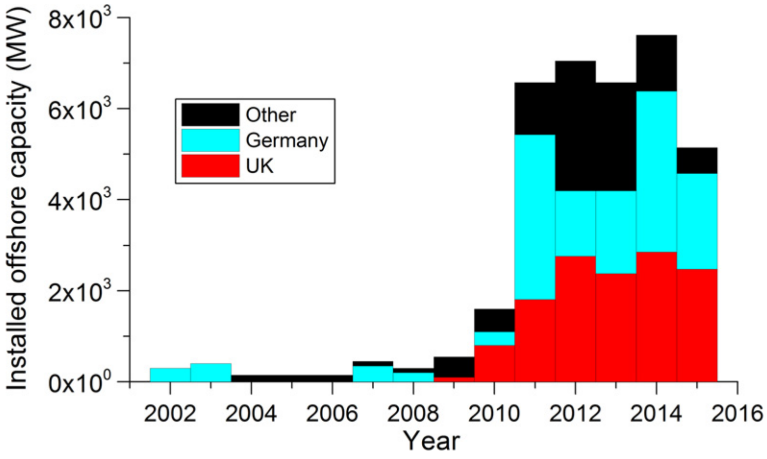

Figure 2 Recent and planned offshore wind projects (MW) by expected (or actual) commissioning date. Graph redrawn from von Bismarck et al. (2009). Also see data in **Table 2**. Reproduced from von Bismarck, M., A. Gurung, M. Liebreich, and C. Greenwood, 2009: Green investing. Towards a clean energy infrastructure. *Energy Bull.*, **3**, 6–23.

key wave characteristics can be described using Airy wave theory (US Army Corps of Engineers 2008), in which the velocity potential is given by

$$\Phi(x, y, z; T) = \frac{Hg}{2\omega_s} D(z) \sin(kx - \omega_s T) \qquad [2]$$

where

H is the wave amplitude

g is the acceleration due to gravity

ω_s is the frequency $(2\pi/T)$

$D(z)$ is the depth decay function given as

$$D(z) = \frac{\cosh[k(z+d)]}{\cosh(kd)}$$

k is the wave number $(x\cos\theta + y\sin\theta)$

λ is the wavelength

x,y are the perpendicular axes with $z = 0$ at the still water level

θ is the direction of the wave relative to the x-axis

d is the water depth

T is the wave period

For Airy waves, the horizontal velocity (u_w) and acceleration (a) are given by

$$u_w = \frac{HgT}{2\lambda} \frac{\cosh[2\pi(z+d)/\lambda]}{\cosh(2\pi d/\lambda)} \cos\theta \qquad [3]$$

$$a = \frac{HgT}{2\lambda} \frac{\sinh[2\pi(z+d)/\lambda]}{\cosh(2\pi d/\lambda)} \sin\theta \qquad [4]$$

Waves propagate at the phase speed (c_p) (i.e., at a velocity, v), which is given by

$$c_p = \frac{\omega_s}{k} = \frac{\lambda}{T} \qquad [5]$$

The actual electrical energy that can be produced by a wave energy converter (WEC) is a function of the entire directional wave spectrum (Mackay et al. 2010). However, the significant wave height H_s is a key determinant of the energy in the wave field, and may be operationally estimated as four times the standard deviation of wave height (i.e., $4\sigma(H)$). Where spectral information regarding the wave field is unavailable, for deep ocean 'Airy' waves (where the wavelength of the wave is small compared to the depth of the water) the power in the waves (the wave energy flux, P) and the average energy density per unit area of waves on the water surface (E) may be approximated using H_s and the wave period (T) as follows:

$$P = \frac{\rho g^2}{64\pi} H_s T \qquad [6]$$

$$E = \frac{\rho g}{16} H_s^2 \qquad [7]$$

H_s can also be used to approximate the most probable maximum wave height in a given sea state for 1000 waves using (van der Temple 2009)

$$H_{\max} = 1.86 H_s \qquad [8]$$

Naturally, the wave field is also a function of bathymetry and as waves approach the shoreline the seabed begins to influence their speed such that at water depths less than one-quarter of the wavelength, the wave velocity (v) is

$$v = \sqrt{gd} \qquad [9]$$

As with wind turbines, wave power technologies capture part of this energy and reduce wave heights in the lee of the device. However, unlike wind, there is no single preeminent technological solution to harnessing energy from waves and tidal currents (Barthelmie et al. 2000; Mueller and Wallace 2008; Price 2009; Heath 2012). Kinetic wave energy devices generally fall into one of three classes:

- Attenuators, wherein long multisegment floating structures are placed in parallel to the direction of the waves. Flexing of the structures due to the passage of waves causes expansion and contraction of segment connections, which power hydraulic pumps and a generator.
- Point absorbers, where a floating device (e.g., a floating buoy within a fixed cylinder) absorbs energy from the oscillation of the water surface causing a stretching and compressing motion, which is used to drive electromechanical or hydraulic energy converters.
- Termination wave devices, in which water enters through a subsurface opening into a chamber with air trapped above it, the rise and fall of the water within the chamber acts like a piston forcing air through an opening connected to a turbine, which then generates electricity.

An additional class of device relies on using wave overtopping to collect water that then flows through a traditional low-head hydropower turbine. While these were originally coastal type devices like the TAPCHAN prototype in Norway, it is also the mechanism used by the Wave Dragon (Tedd and Kofoed 2009).

3.04.2.2.2 Resource Magnitude

The range of estimated theoretical wave energy resource potentials available in the literature is comparatively large. One estimate of theoretical potentials for wave energy of 7400 EJ (Exa-J = 10^{18} J, equivalent to 234 TWh year^{-1}) was approximately equal to that for wind energy (Resch et al. 2008). Due to the comparative nascent status of wave energy deployment it is difficult to assess the global technical resource with any confidence, but one analysis determined that it exceeds 2.7 TW (Jacobson and Delucchi 2011). **Table 3** summarizes one analysis of the technically achievable wave power resource (Frefri and Infield 2008). This assessment is in accord with that of Jacobson and Delucchi (2011) if the far offshore is included.

Table 3 Total global technically achievable wave power resource (Frefri and Infield 2008)

Location	*Global potential (GW)*
Shoreline	1–50
Near shore	10–500
Offshore	200–5000

Data from Frefri, L., and D. Infield, 2008: *Renewable Energy in Power Systems*, John Wiley and Sons, Ltd., Chichester, U.K.

As with the wind resource there is tremendous spatial variability in wave energy density (Arinaga and Cheung, 2012). One global analysis of wave energy resources found largest resources in the latitude zone 40–60°S, and specifically off the SW coast of Australia where maximum wave energy flux exceeds 125 kW m^{-1} of wave crest. In the northern hemisphere, the highest average wave power is focused on regions within the North Atlantic – specifically off the coast of Iceland and to the west of the British Isles (Cornett 2009; Arinaga and Cheung 2012). Many individual countries and regions have also assessed the available wave energy resource (Zhang et al. 2009; Hughes and Heap 2010; Lenee-Bluhm et al. 2011).

Naturally, like the energy density of the near surface atmospheric flow, the wave field (and by association the wave energy density) at a specific location exhibits variability on a wide range of time scales from seconds to decades, though in the case of waves the high frequency variability is suppressed relative to the atmosphere.

3.04.2.2.3 Current Status of Wave Energy Deployment

Wave energy projects are largely in the research and demonstration phase and indeed a number of large-scale wave energy prototypes have been tested (Cruz et al. 2008; Mueller and Wallace 2008). In 2008, the world's first wave commercial-scale power plant was developed off the coast of Portugal at Aguçadoura. The first phase of the development uses attenuator technology and has a capacity of 2.25 MW. Due to technical and financial issues the project was delayed, but plans are underway to expand the project under new management. Further devices from the same company (Pelamis) are under test at the European Marine Energy Center in Shetland, UK. Point absorber technology has been used by Ocean Power Technology (OPT) with their power buoy that was deployed off Oahu, Hawaii, and grid connected in 2010. A 500 kW system based on the oscillating water column concept has been in operation since 2000 on the Scottish island of Islay (Heath 2012). A new round of investment in wave energy technologies is expected, but issues of the cost of electricity, reliability, and durability of the devices and project finance continue to hamper larger scale developments and deployment (Renewable Energy World 2011).

3.04.2.3 Tidal and Sea Currents

3.04.2.3.1 Harnessing the Power of Tides and Sea Currents

Tides are cyclic variations in the level of water bodies due principally to the gravitational force of the moon. Thus one advantage of tidal energy over other ocean renewable resources is it is highly predictable (Jahromi et al. 2011). Two approaches are available to harness tidal power; the first relies on deployment of barrages to establish a head of water, which can power a turbine (and thus to work in a manner similar to most hydroelectric schemes), and the second approach harnesses local tidal currents and thus exploits the water currents associated with tides (Barthelmie et al. 2000; Blanchfield et al. 2008; Denny 2009; Rourke et al. 2010; Atwater and Lawrence 2011).

Tidal turbines share many similarities to wind turbines; however, due to the higher density of sea water they can produce 800–900 times more power when compared to an equivalent wind turbine of similar size operating at the same speed (Jahromi et al. 2011). A wide range of possible technologies have been proposed to determined the magnitude of the tidal current resource and to harness tidal currents (Walkington and Burrows 2009; Rourke et al. 2010), but as discussed below, these are currently in the demonstration phase.

The energy available from a tidal barrage is given by

$$E = \frac{1}{2}A\rho g h^2 \qquad [10]$$

where

A is the horizontal area of the barrage basin

h is the range in water level from high to low tide

Ocean currents can additionally be harnessed (Bernitsas et al. 2008; Bahaj 2012) and have the advantage that they are relatively well predicted since they are largely gravitationally forced. The theoretical resource has been estimated to be 5 TWh (Tester et al. 2005). However, there are no commercial grid-connected turbines generating electricity from ocean (or sea) currents currently and thus they will not be discussed further here.

3.04.2.3.2 Resource Magnitude

It is difficult to assess the total global tidal resource, but one estimate suggests that the potential mean power and potential annual electricity production from tidal barrage sites that have been extensively surveyed to date exceed 65 TWh and 600 TWh year^{-1}, respectively (Rourke et al. 2010). The theoretical potential tidal resource as estimated by the IEA exceeds 800 TWh year^{-1} Table 4 (IEA/OECD 2007). The tidal resource is highly spatially variable, but countries with large estimated resources include the United Kingdom, Ireland, Canada, and China (Burrows et al. 2009; O'Rourke et al. 2010). For example, in Ireland, tidal power could contribute up to 10% of national electricity use (O'Rourke et al. 2010) and the total theoretical potential tidal resource along the coastline of China has been estimated to exceed 580 TWh year^{-1} (Liu et al. 2011).

Table 4 Comparison of potential global electricity production estimates from ocean energy sources (IEA/OECD, 2007). For comparison, the theoretical total wave energy potential was estimated to be 29 500 TWh year^{-1} in the 2012 IPCC summary, while the thermal energy resource was estimated to fall toward the lower end of a cited range of 30 000–90 000 TWh year^{-1} (Edenhofer et al., 2012)

Method	*Potential production (TWh year^{-1})*
Tidal current	>800
Salinity gradient	2000
Ocean wave	8000–80 000
Thermal energy	10 000

Data from IEA/OECD, 2007: *Energy Technologies at the Cutting Edge*. International Energy Technology Collaboration–IEA Implementing Agreements, Paris, France.

3.04.2.3.3 Current Status of Tidal Power

According to some estimates, the cost assessments for tidal barrages generally indicate economic feasibility at about 5 m tidal range (Price 2009). The only large-scale tidal barrage power plant was built in La Rance, France in 1966. The mean tidal range at this site is 7 m and the tidal power station has an installed capacity of 240 MW. The approximate annual electricity production from this tidal barrage is 544 GWh (Kerr 2005). The next largest facility is located at Annapolis Royal, in Nova Scotia. Built in 1984, it has a capacity equal to 18 MW (Rourke et al. 2010). A further large (254 MW) tidal barrage project in Korea was projected to be completed in 2010 (Bae et al. 2010), but remains unfinished as of early 2012. There are also several smaller projects in China (Liu et al. 2011) and Atlantis Resources recently announced it will install a 50 MW tidal farm in the Gulf of Kutch on India's west coast, with construction starting early in 2012. Other locations for tidal barrages have been proposed and sites for development including the Bay of Fundy in Canada, which has a tidal range of 10 m and the Severn Estuary in the United Kingdom (Clery 2008), which has a mean tidal range of 8 m (Barthelmie et al. 2000). A number of smaller capacity tidal stream energy converters have been deployed, including a 1.2 MW device in Strangford Lough, Northern Ireland (Atwater and Lawrence 2011; Devine-Wright 2011). China has also deployed several small-scale devices including both bottom-mounted and floating devices (Goa 2011).

In the global analysis of the IEA, tidal and wave energy produced just 0.6 TWh of electricity in 2007, but it was projected to increase to almost 13 TWh by 2030 (International Energy Agency 2011).

3.04.2.4 Current Challenges to Large-Scale Deployment of Renewable Ocean Technologies

A number of challenges confront large-scale implementation of technologies to harness ocean energy resources. These include but are not limited to intermittency, cost, and environmental impacts. Brief description of, and possible mitigation options for, these issues is given below.

Virtually all renewable energy resources exhibit some degree of intermittency. Addressing issues of intermittency indeed may be key to facilitating achievement of the goals and projections for ocean energy technologies articulated by the IEA and others. Concerns over the security of electric supply, combined with increasing pressure to tackle climate change, have forced many European countries to urgently reevaluate their energy strategies, and to propose a pan-European electricity Supergrid to act as a transmission network (Macilwain 2010), enabling the secure distribution of electricity between countries and to facilitate flexibility in electricity generation and supply management. It is often argued that introduction of large-scale wind or wave power will lead to excessive demand for spinning reserve due to intermittency of supply. However, given the spatial scales of synoptic-scale weather systems, the spatial autocorrelation function for wind is only a few hundreds of kilometers (Pryor et al. 2006a), thus a distributed and highly interconnected network exhibits much smaller temporal variability in electricity supply. Enhancing the distribution network as proposed with the Supergrid will not only facilitate integration of renewable energy supplies, but may also increase resilience to extreme events (e.g., extreme wind storms). Such policies could also be coupled with local actions such as deployment of increased smart-metering systems (Zhang and Nuttall 2011) that coupled with dynamical (real-time) pricing regimes allow consumers (private and commercial) to determine usage based on price. Although refinements may be necessary for full-scale operation, this mechanism has been shown to be effective in moderating peak demand in small-scale deployments (Strengers 2010). An alternative strategy to issues of deliverability of electricity is to deploy storage technologies. At least some of these technologies are coincident or complementary with ocean renewable energy converters, for example, where technologies are deployed that can store water until electricity demand exceeds some threshold, at which point it is released to increase electricity supply (Clarke et al. 2006; Price 2009).

Externalities and other considerations influence actual energy policy, but cost is a vital component of the adoption of any technology. However, pricing is a function of complex subsidies, discounting rates and assumptions regarding fuel costs. Typically for the renewable energy technologies the majority of the costs are upfront capital costs while the fuel is free. Thus the degree to which future expenditures or costs are related to current value is critical to assessing the average lifetime cost per megawatt hour of a given electricity source (Allan et al. 2011). There is a need, therefore, to ensure robust benchmarks, externality costs, and full life-cycle analyses are applied when assessing the economic viability of different electricity generation technologies.

All energy sources for electricity generation result in environmental impacts and other externalities (Gohlke et al. 2011). Possible impacts of deployment of ocean renewable technologies generally fall within four principal areas of concern: (i) acoustics and specifically noise (which is largely confined to the construction phase), (ii) introduction of electromagnetic fields, which can be minimized (though not completely eliminated) by shielding of cables, (iii) alteration of the dynamics of the environment via obstruction to the flow and possible collision of organisms with support structures, and (iv) alteration of local species composition (Gill 2005). Accordingly, environmental impact assessments are routinely conducted for offshore wind deployments, tidal barrages, and deployment of wave technologies (Boehlert and Gill 2010).

Naturally not all impacts on the marine environment can be eliminated, but equally not all impacts may be negative. For example, tidal barrages greatly alter the ecology of the tidal estuary, but these changes lead to both benefits and negative impacts depending on the species under consideration (Price 2009). Analyses of existing offshore wind farms in Denmark have indicated fewer negative ecological consequences than were projected during the planning phase in terms of, for example, the impact of noise on marine mammals (Tougaard et al. 2009) and alterations of bird migration trajectories (Masden et al. 2009). Further, according to some assessments, large-scale deployment of wave technologies with appropriate planning, mitigation, monitoring etc. have the potential to offer benefits to marine birds in the future (Grecian et al. 2010). Technological advances, harmonization of environmental impact assessments, and setting of uniform standards will likely assist in optimal siting and technology design/implementation to minimize environmental effects from deployment of the ocean renewable technologies.

3.04.3 How Might Changes in Climate Statistics Influence Ocean Renewable Energy?

As discussed in Section 3.04.2 Resource Estimates and Status of Deployment, other than hydropower, wind power is the most mature and has the greatest global penetration of electricity generation of current renewable sources, thus much of the remainder of this chapter will focus on wind energy.

3.04.3.1 Changes in the Resource Magnitude

Alterations in local and regional climates may impact ocean renewable energy industries by changing the geographic distribution and/or the inter- and intra-annual variability of the resource. Relative to wind and wave energy, the influence of climate nonstationarity on tidal resources is likely only to be very modest, and would likely derive principally from changes in operating conditions (see Section 3.04.2).

As described above, wind and wave climates are highly coupled physically. Since the wind and wave resource are strongly linked to atmospheric circulation patterns, changes in the spatial–temporal distribution of resources is possible (Weisse and von Storch 2010). However, at least within the midlatitudes the dynamical linkages between any changes in climatology and the near surface flow are complex. In midlatitude regions where the atmospheric flow is not dominated by thermotopographic effects, the wind climate is principally determined by the synoptic-scale circulation and thus transitory anticyclone and cyclones. Cyclone development is a baroclinic process and thus it is relatively insensitive to large-scale (equator to pole) temperature gradients and may be more strongly influenced by upper tropospheric thermal gradients than possible decreases in near surface temperature gradients (Held 1993). Steering of those systems is influenced by the large-scale thermal gradient, but this link is also indirect, and there may be a stronger influence of higher water-holding capacity and energy availability due to the phase transfer of water (Chang et al. 2002), or changes in atmospheric stability due to changing land cover. For these and other reasons, storm track activity cannot be related directly to global-mean surface temperature or large-scale gradients therein (O'Gorman 2011). Thus it is difficult to predict apriori how climatic variability or trends in the coming decades may be manifest in terms of changing ocean energy resources. In the following subsections, we summarize some of the research that has been conducted to date regarding possible impacts of climate nonstationarity on ocean energy resources.

3.04.3.1.1 Historical Tendencies and Variability

Assigning causality to temporal tendencies in wind or wave climates is very difficult. Key challenges to understanding how climate nonstationarity has or may influence the spatial and temporal distribution of wind and wave climates and thus the wind and wave resource, derive from the large inherent variability in many locations and a lack of complete understanding the sources of current variability in near surface wind regimes (and by association wave climates).

Although the magnitude of the temporal trends in ocean winds and waves is sensitive to the precise data set used and data homogenization procedures applied (Tokinaga and Xie 2011a; Wentz and Ricciardulli 2011; Young et al. 2011a,b), the majority of analyses of recent historical tendencies in oceanic near surface wind speeds and wave climates have generally indicated trends toward increased values. For example, an analysis of wind speeds and wave heights from a 23 year record of satellite altimeter measurements indicate increasing wind speeds over the majority of the world's oceans (of up to 5% per decade for 1991–2008) (Young et al. 2011b). The same study found a smaller magnitude increases in mean significant wave height, though the tendencies were not statistically significant. Extreme values (99th percentile values) of both parameters also exhibited increases. In the case of 99th percentile significant wave height, the tendencies were mostly positive in the North Atlantic, particularly off the coast of Europe (Young et al. 2011b). Based on data from passive microwave satellites, another analysis found that average over all oceans the trend in wind speeds was $+0.08\ \mathrm{m\ s^{-1}\ decade^{-1}}$ (1.0% per decade) during 1987–2006 (Wentz et al. 2007). There is some evidence of a weakening of trade winds over the tropics (Tokinaga and Xie 2011b), but positive tendencies have generally been found to be largest in the higher latitudes (Wentz et al. 2007; Young et al. 2011b). There is also some evidence from deep water wave buoys for increased mean significant wave height in the north Pacific during the last three decades and for an increase in mean wave energy along the west coast of North America (Seymour 2011). Conversely, an analysis of wave climates in the northwestern Mediterranean Sea over the last 44 years found no significant temporal trends in annual mean and maximum energy, but an increase in the storm energy of events from the south (Casas-Prat and Sierra 2010).

Because the wave field is not instantaneously coupled to the atmospheric flow and is a function not only of wind speed, but also, for example, wind direction due to the influence on over–water fetch, tendencies in wind and wave fields need not be linearly related. For example, one analysis of future wave heights in the North Sea indicated evidence for increases of 18%, while the 99th percentile wind speed increased by only 7% (Grabemann and Weisse 2008). Further, an analysis using the third-generation wave model WAM over the Baltic Sea for 1970–2007 found that when wind fields constructed on the basis of geostrophic winds were applied to the WAM model, a complex spatial pattern of changes in basic wave properties (average and extreme wave heights and wave periods) evolved. The study found annual mean significant wave height decreased by more than 10% in the south of the Baltic Sea (off the coast of Poland) over the period 1970–2007, but increased along the German coastline by an equivalent fraction (Soomere and Raamet 2011).

A number of studies have examined possible changes in the number, intensity, or location of storm tracks (preferred regions of extra-tropical cyclone activity) and have found extra-tropical cyclone activity is strongly related to large-scale modes of climate variability (e.g., El Niño-Southern Oscillation (ENSO), the Arctic Oscillation (AO), the North Atlantic Oscillation (NAO), the Pacific–North American (PNA) index, and others), which results in large intra-annual, inter-annual, and even inter-decadal variability in storm activity which is also manifest in wind and wave climates (Weisse and von Storch 2010). For example, inter-annual variability in wind energy density across much of Europe is of the order of ±10–15%, while the inter-decadal variability is approximately ±30% (Pryor and Barthelmie 2010). This time-scale of variability is particularly marked in the midlatitude regions influenced by storm tracks and greatly confounds detection of a climate change signal. A strong signal for continued influence of internal climate variability is also manifest in wind regimes over Europe drawn from climate simulations of the 20th century (Pryor et al. 2012a).

3.04.3.1.2 Future Scenarios

Developing scenarios of possible future wind and wave resources is challenging. The ability of dynamical or statistical downscaling tools to generate robust higher resolution scenarios of near surface climate parameters in the coming decades from climate simulations conducted using coupled Atmosphere–Ocean General Circulation Models (AOGCMs) has been challenged (Pielke and Wilby 2012). Some analyses have indicated downscaling tools applied to wind climates exhibit some skill the historical period particularly over the land surfaces and in the coastal zone (Winterfeldt et al. 2011; Pryor and Barthelmie 2012a; Pryor et al. 2012b,c). However, the variability in wind climate projections for future periods due to variability in the AOGCMs and downscaling methodology applied is of comparable magnitude to the climate change signal present in future simulations (Pryor et al. 2005a,b, 2009; Pryor and Schoof 2010; Pryor and Barthelmie 2011) (see **Table 5**). Further, while model transferability experiments have demonstrated that Regional Climate Models (RCMs) can simulate some climate conditions beyond those in the historical period in the region of origin (e.g., Jacob et al. 2012), there remain concerns about the ability of the model-chains to capture possible changes in the climatology of near surface parameters. Thus the scenarios provided in Sections 3.04.1 and 3.04.2 should be interpreted as providing, at best, a subset of possible future conditions.

It is important to note that AOGCMs are variable in their ability to reproduce the modes of inter-annual variability (e.g., the teleconnection indices describe above) (Stoner et al. 2009; Harding et al. 2011), and that AOGCMs tend to underestimate both inter-annual and intra-annual variabilities of near surface wind speeds relative to those from reanalysis data sets (Chen et al. 2012). Further, wind and wave climates in the coastal zone vary on temporal and spatial scales below those typical of climate models (Barthelmie et al. 2007). With those caveats in mind, research to date suggests multiyear annual mean wind power densities over Europe and North America will likely remain within ±25% of historical values during the current century (Breslow and Sailor 2002; Pryor et al. 2005a, 2006b;

Table 5 Sensitivities of downscaled 90th percentile wind speed (used as an analog for the wind energy density) for 46 stations across Northern Europe from the probabilistic approach of Pryor et al., (2005b). The results show the total range of differences in the 90th percentile wind speed computed for 2081–2100 versus 1961–1990. Thus if the range is ±*X*%, at all stations the projected period lies with *X*% of conditions during the historical period. Table adapted from Pryor and Schoof (2010)

Parameter	*# AOGCMs*	*SRES*	*Range of estimates*
AOGCM architecture	10	A2	±25% for 45 of 46 stations
Stochastic w/in AOGCM	5 (Copenhagen station)	A2	95% of realizations w/in ±10%
SRES	1 (ECHAM5)	A2, A1B, B1, Commit	±15%
AOGCM member	1 (ECHAM5)	2 × 20th century	±15%

Key of uncertainties assessed: (i) AOGCM architecture: i.e., variations in the downscaled results computed over all stations for downscaling using output from 10-AOGCMs. These variations reflect the influence of the AOGCM from which the predictors were obtained. (ii) Stochastic w/in AOGCM: i.e., variations in the downscaled results computed over all stations that derive from 1000 bootstrapped resampled time series of the predictors. These variations reflect the influence of white noise in a given AOGCM simulation. (iii) SRES: i.e., the emission scenario applied in the AOGCM simulations. (iv) AOGCM member: i.e., the variation that derives from differences in the AOGCM predictors, due to small perturbations in the conditions from which the AOCGM evolves.

Modified from Pryor, S. C., and J. T. Schoof, 2010: Importance of the SRES in projections of climate change impacts on near-surface wind regimes. *Meteorol. Z.*, **19**, 267–274.

Walter et al. 2006; Bloom et al. 2008; Sailor et al. 2008; Pryor and Schoof 2010; Pryor and Barthelmie 2011). Using output from the RCM simulations conducted under the North American Regional Climate Change Assessment Program (NARCCAP) (Mearns et al. 2009), mean annual energy density (at a nominal height of 10-m) for 2041–2062 was computed for all partly or totally offshore grid cells within 100 km of the US coast. The two RCM–AOGCM combinations selected for this analysis are RegCM3 = Regional Climate Model 3 (Pal et al. 2007) nested in the GFDL = Geophysical Fluid Dynamics Laboratory model (CM2.1) (Delworth et al. 2006) and CRCM = Canadian Regional Climate Model (de Elia and Cote 2010), nested in CGCM3 = Canadian model Version 3 (Scinocca et al. 2008). Both of these model combinations exhibit mean energy density fields over North America that exhibit a relatively high degree of accord with independent wind resource estimates (Pryor and Barthelmie 2011). The results of analyses of the difference in grid-cell averaged energy density in simulations of 2041–62 relative to 1979–2000 indicate that the projected mean energy density at the majority of coastal locations lies within 10% of historical values (**Figure 3**). However, this analysis also reemphasizes the importance of the precise

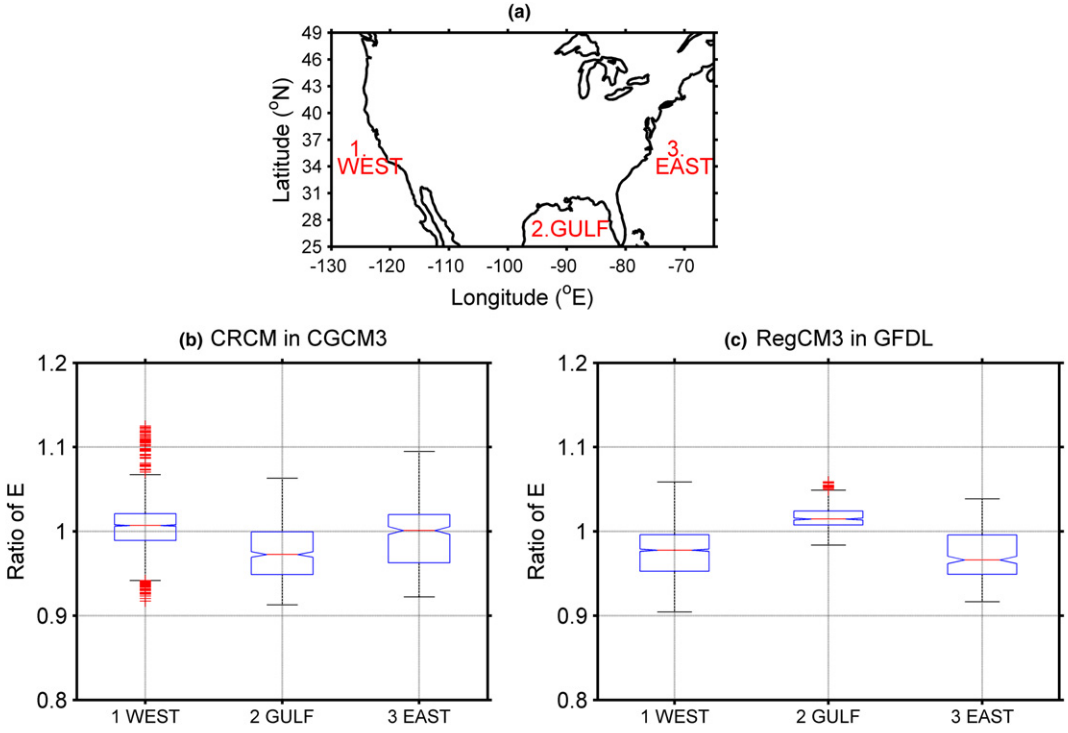

Figure 3 Box-plots of the ratio of energy density (2041–62 versus 1979–2000) in coastal grid cells (i.e., grid cells within 100 km of the coastline) in simulations from (b) Regional Climate Model 3 (RegCM3) nested in the Geophysical Fluid Dynamics Laboratory (CM2.1) AOGCM and (c) Canadian Regional Climate Model (CRCM) nested in the Canadian AOGCM version 3 (CGCM3). These simulations were conducted under the North American Regional Climate Change Assessment Program (NARCCAP), and the future period assumes greenhouse gas emissions according to the A2 SRES. Frame (a) shows the regions used to summarize the data in frames (b) and (c).

AOGCM–RCM combination used in the scenario development in determining the sign and magnitude of change. In simulations using the CRCM coupled to the CGCM3 AOGCM, the majority of locations along the West Coast of the USA exhibit marginally higher energy density in the mid-century, while in the simulations from RegCM3 nested within GFDL AOGCM the converse is true (**Figure 3**). Also, in both sets of simulations, the climate change signal is considerably smaller than the inter-annual variability in the historical period 1979–2000. Naturally, this does not imply wind resources in the water surrounding the contiguous USA will not deviate from historical values, but at least in the medium term (i.e., the mid-21st century) these model simulations do not indicate evidence for substantial changes.

Climate change analyses that have been conducted to date with a focus on sea state generally indicate projected increases in wave activity in the Northeast Atlantic. One study reported the current 20 year return period wave may be expected to occur every 4–12 years by 2080 (Wang et al. 2004). In the Baltic Sea another study found that the annual mean significant wave height and the 90th percentile wave height may increase by about 0–0.4 and 0–0.5 m, respectively, over the course of the 21st century (Meier 2006). In contrast, simulations for the Mediterranean Sea using the WAM model mainly indicated lower significant wave heights under future climate change scenarios (Lionello et al. 2008). These changes are indicative of (and consistent with) an observed tendency in the majority of AOGCMs to displace storm tracks northward over the North Atlantic under most reasonable climate forcing scenarios (Bengtsson et al. 2006; Giorgi and Lionello 2008). A study to develop wave climates around Japan under climate change scenarios using the SWAN model found a 10% potential increase in the future wind speed of typhoons resulting from the warming of surface sea temperatures can lead to a 21% increase in the significant wave heights generated by these winds (Takagi et al. 2011).

Consistent with the discussion above regarding the relatively large uncertainties in simulating wind and wave conditions using existing climate models, it should be noted that there is not always consistency between results from different studies focused on projecting potential changes in wave height and storm surges. For example, one study of the North Sea in which wind fields from HadAM3H and ECHAM4/OPYC3 were used suggested most areas would experience an increase in significant wave height (H_s) of 5–8% by the end of the 21st century (Grabemann and Weisse 2008). However, a second study that based on a 17-member ensemble of North Sea water levels for 1950–2100 generated using a surge model of the North Sea with output from the ECHAM5/MPI-OM AOGCM forced with the A1B climate forcing scenario indicated no statistically significant change in the 10 000 year return values of surge heights along the Dutch during the 21st century (Sterl et al. 2009). A third study using the ECHAM5 indicated the majority of increases in storm surges during the 21st century may be focused in the northeast North Sea along the west cost of Denmark (Weisse et al. 2009). The last result is in accord with the majority of analyses of potential storm-surge statistics for the northwest European shelf, which have generally indicated increased storm-surge magnitudes (Weisse and von Storch 2010).

An early study which used output from the CGCM2 AOGCM indicated large magnitude changes in H_s off the West Coast of Europe during winter by the end of the century and further documented that the magnitude of changes was a strong function of the climate forcing scenario applied (Wang et al. 2004). In accord with lower wave heights and potentially more northward storm tracks, storm surges in the Mediterranean are projected to decrease in both frequency and intensity in the 21st century (Marcos et al. 2011).

Few studies have explicitly sought to quantify the impacts of climate change on wave energy generation from WEC. One analysis focused on Cornwall, UK found that changes in wind speeds when applied to a wave model found available wave power increased by 2–3% in the A1B climate forcing scenario but decreased by 1–3% in the low climate forcing scenario (B1 SRES). The WEC energy yield decreased by 2–3% in both A1B and B1 scenarios, due to the relatively low efficiency of energy extraction from steeper waves by the specific WEC considered (Reeve et al. 2011).

Whether changes in the global climate system will be manifest as changes in the inter-annual, seasonal, and/or diurnal variability of wind and/or wave resources in given locations are unclear. Wind climates in northern Europe exhibit seasonality with highest wind speeds during the winter (Rockel and Woth 2007) and some analyses of storminess in the Northeast Atlantic (1874–2007) exhibited notable differences temporal trends in winter (DJF) and summer (JJA) (Wang et al. 2009). Other analyses have indicated increases in wave heights in winter in parts of Europe with mainly decreases in wave height in the other seasons (Zacharioudaki et al. 2011). However, relatively little research has focused on potential changes in the seasonal variability of wind and wave resources, and given the inability of downscaling methods to reproduce historical wind and wave climate these projections must be viewed as highly uncertain.

In considering possible impacts of climate nonstationarity on extraction of ocean energy resources it is worthy of note that typical lifetimes of current wind installations are 20–30 years (though offshore foundations have longer lifetimes) and if climate nonstationarity leads to changes in the wind, wave, or current resource (or operating conditions) on time scales longer than a few decades, the respective industries may be able to adapt either through improved technology or by shifting the location of the energy extraction projects.

3.04.3.2 Changes in Operating Conditions

The primary mechanisms by which tidal installations might exhibit climate sensitivity derive from possible changes in sea level and the frequency and/or magnitude of storm surges. Sea level rise over the course of the 20th century was estimated to be $1.8 \pm 0.5\ \mathrm{mm\ year^{-1}}$ (i.e., 0.18 m) in the Fourth Assessment Report of the IPCC (Bernstein et al. 2007) and projections of a further 0.21–0.48 m rise have been made for the end of the 21st century (Grinsted et al. 2009). However, some hypothesize that projections of global sea level change cited in the IPCC assessment may be biased low by up to a factor of three (Rahmstorf 2007a,b, 2008, Grinsted et al. 2009), and that sea level rise along the east coast of the USA may exceed prior estimates (Yin et al. 2009).

Making detailed regional sea level projections is confounded by the influence of storm surges, atmospheric flow, and eustatic adjustments. For example, in the Baltic Sea, it has been reported that a global-mean sea level rise of 50 cm from 1990 to 2080 would lead to a sea level rise of 33–46 cm in Danish waters, and may reverse the historical decline in mean sea level in the Gulf of Finland (Graham et al. 2008). Such changes may have implications for tidal characteristics in specific locations, though such changes are likely to be small (Weisse and von Storch 2010). These changes may ultimately influence the design/operation of tidal barrages, but relatively little is known about such impacts. A discussion of the possible influence of climate nonstationarity on the frequency or intensity of storm surges is given below.

Offshore wind turbines experience site-specific environmental loads from wind, wave, sea currents, sea ice, and scour resulting in changing soil dynamics. Thus at a minimum when wind turbines are deployed offshore the extreme load cases considered in the design and selection of the turbine and foundation must include the contributions from the atmospheric and hydrologic components (Agarwal and Manuel 2008). Similar loading analyses are also crucial to wave energy devices.

The primary external conditions that influence the structural integrity of a wind turbine are the normal and extreme wind conditions. That is, loads relating to external conditions can be divided into extreme loads, which arise mainly from extreme (i.e., inherently rare) events with return periods of 1–50 years (described further below), and fatigue loads (Dekker and Pierik 1999), which are primarily determined by the mean wind speed and the standard deviation of wind speed fluctuations, which are strongly related to site turbulence levels (Frandsen 2007).

One of the key design standard criteria for wind turbines is linked to the 50 year return period 10 min sustained wind speed (U_{50yr}). Preliminary analyses from both dynamical and empirical downscaling over Northern Europe exhibit some evidence for increased magnitude of these wind speed extremes (Makkonen et al. 2007; Haugen and Iversen 2008; Pryor et al. 2012a). However, as described above, the internal variability is very large and there are substantial uncertainties in extrapolating to low probability events. As an example, an hourly average U_{50yr} was derived for RCM grid cell within a Northern European domain (51–71°N 3–33°E) using 30 year time slices from continuous simulations (1961–2100) from the HIRHAM5 RCM nested within the ECHAM5 AOGCM run for the A1B emission scenario (SRES). The 50 year return period value and associated uncertainty for each time slice was compared with the value derived for the control period (1961–90) (Pryor et al. 2012a). The fraction of the total number of grid cells that exhibits a U_{50yr} from a given 30-year period that is (i) above or below the U_{50yr} estimate from 1961 to 1990 and (ii) above or below the 95% confidence intervals on U_{50yr} estimate from 1961 to 1990 was then computed. The results of this analysis indicate that natural (inherent) variability in extreme wind speeds exceeds a climate change signal until toward the end of 21st century and that even for the last 20 years of 21st century, only a fairly small fraction of grid cells (approximately 22%) exhibit U_{50yr} that lies beyond the 95% confidence interval derived for the control period (**Figure 4**). Further the magnitude of changes (up to $+3\ \mathrm{m\ s^{-1}}$) are relatively modest compared to the uncertainty inherent in calculating U_{50yr} and are likely of lesser magnitude than the over estimation of U_{50yr} within the wind turbine design standards (Pryor and Barthelmie 2012a).

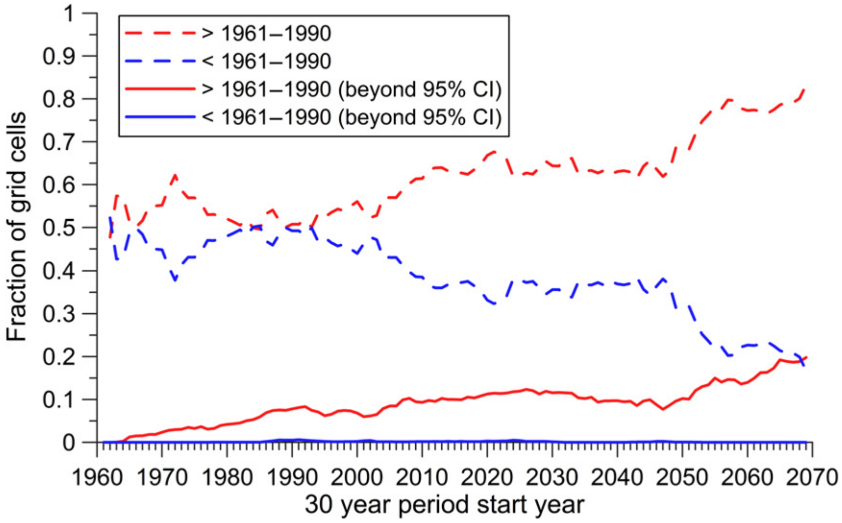

Figure 4 Fraction of the total number of grid cells in simulation of conditions over Northern Europe (51–71°N 3–33°E) using HIRHAM5 (May 2008) coupled to the ECHAM5/MPI-OM1. Atmosphere–ocean global climate model (Roeckner et al. 2006) that shows U_{50yr} above or below the value for 1961–90. U_{50yr} is computed for each grid cell and time period independently and then the data are shown as the fraction of total grid cells that show a U_{50yr} from a given 30-year period that is (i) above or below the U_{50yr} estimate from 1961 to 1990 (>1961–90 and <1961–90, respectively), and (ii) above or below the 95% confidence intervals (CI) on U_{50yr} estimate from 1961 to 1990 (beyond 95% CI). The AOGCM simulation was conducted for the A1B emission scenario (Nakicenovic and Swart 2000).

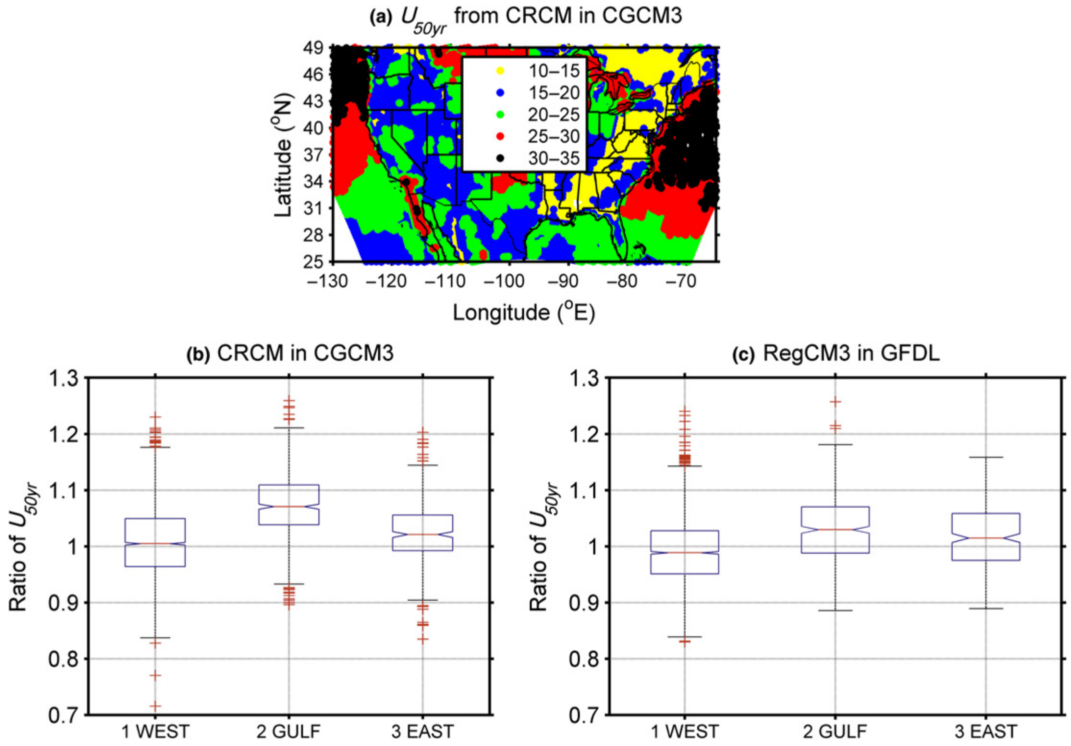

Figure 5 (a) Fifty-year return period sustained wind speed (U_{50yr}) (m s^{-1}) at 10 m over the contiguous USA and surrounding waters during the historical period (1979–2000) derived from output from CRCM nested in the Canadian AOGCM version 3 (CGCM3). The two lower frames show box-plots of the ratio of U_{50yr} (2041–62 versus 1979–2000) in coastal grid cells (i.e., grid cells within 100 km of the coastline) in simulations from (b) RegCM3 nested in the Geophysical Fluid Dynamics Laboratory (CM2.1) AOGCM and (c) CRCM nested in the CGCM3. The regions denoted in frame (b) and (c) are as in **Figure 3**. These simulations were conducted under the NARCCAP, and the future period assumes greenhouse gas emissions according to the A2 A1B emission scenario.

A similar analysis of possible changes in U_{50yr} was conducted using the same NARCCAP RCM simulations as described above for the wind resource. When the results of those calculations are conditionally sampled to select only offshore grid cells within 100 km of the US coast, and U_{50yr} estimates for 2041–62 are compared to 1979–2000, the results indicate a weak tendency toward increased extreme wind speeds, although most grid cells show <20% change in absolute magnitude of extreme wind speed (Figure 5).

These analyses of extreme wind speeds derived using output from RCMs thus may be taken to indicate little change in extreme wind loading. However, there are some important caveats that should be applied to these sorts of analyses: The current formulations of RCMs and the application at approximately a 50 km grid-spacing (as in the NARCCAP simulations) preclude treatment of phenomena, such as severe thunderstorms and/or coastal jets that may be associated with damaging winds and high structural loading. Thus further work is warranted to both identify the sources of extreme loading and evaluate the ability to simulate those phenomena in both the current and the possible future climate states, particularly for combined wind–wave loading.

The IEC 61400-1 standard for wind turbine design prescribes a range of additional extreme wind load design cases including extreme operating gust (Revfeim and Hessell 1984; Mitsuta and Tsukamoto 1989; Kristensen et al. 1991), the extreme wind direction change (Dekker and Pierik 1999), the extreme wind shear, and the extreme coherent gust with direction change (Larsen and Hansen 2008). Simulating the physical causes of such events is extremely challenging and quantifying possible changes in these phenomena in the context of climate change represents an even greater challenge to climate science. It is possible that changes in thermal regimes as a results of global climate change may alter the frequency and/or characteristics of mesoscale phenomena such as low-level jets (Smedman et al. 1996; Wu and Raman 1997) and roll vortices (Etling and Brown 1993) that are experienced in the coastal zone. Such changes could considerably impact the local wind resource and/or wind speed profiles and/or extreme wind shear or gusts, but such effects are difficult to quantify and have yet to be given the warranted attention.

Beyond the midlatitudes even less research has been conducted to examine possible changes in ocean technology resources and/or operating conditions as a result of global climate change. In tropical regions, the frequency, duration, intensity, and track for tropical cyclones have a profound impact on the extreme wind and wave climates and energy transfer in the entire global atmosphere. Controversy surrounds identification and quantification of historical and possible future variability and tendencies in tropical cyclone statistics (Weisse and von Storch 2010). Some analyses report evidence for historical increases in Atlantic tropical cyclone and hurricane activity (Emanuel 2005), while others emphasize the high inter-annual variability and resolve no clear tendency in future scenarios of frequency and intensity (Villarini et al. 2011). Thus there appears to be little consensus currently regarding historical tendencies or likely future tropical cyclone climates.

Loading on wind turbines located offshore is a function not only of the wind conditions but also parameters like sea depth and bathymetry, which affect wave height and type (Bergdahl et al. 2007), and/or the action of sea ice (Clausen et al. 2007). Thus the IEC standard 61400-3 for offshore wind turbine has additional requirements for evaluation of external conditions at offshore wind energy sites (Saigal et al. 2007). However, the wind–wave coupling makes it hard to assess possible climate change impacts. Currently the IEC standards conservatively assume that the extreme mean wind and the extreme sea state occur in the same storm system and thus seek to capture the worst-case scenario.

As a first approximation the fatigue wave loading on offshore structures (expressed as a force per unit length on a cylinder) may be computed using Morison's equation as (Burrows et al. 1997; Wolfram 1999)

$$F = \frac{\rho_w}{2} D C_D |u_w| u_w + 0.25 \rho_w \pi D^2 C_M a \qquad [11]$$

where

C_M is the inertial coefficient (∼2) (Veldkamp and van der Tempel 2005)

C_D is the drag coefficient, given by $C_D = \sqrt{\frac{8\sigma_{u_w}}{\pi}}$

D is the diameter of the tubular element (turbine foundation)

u_w is the wave-particle velocity orthogonal to the axis of the tubular element

a is the wave-particle acceleration orthogonal to the axis of the tubular element

ρ_w is the water density

σ_{uw} is the standard deviation of the wave-particle velocity

From the above equation, it can be seen that faster moving, larger amplitude waves exert the greatest force and hence load on wind turbines deployed offshore. However, detailed estimation of sea state and loads are significantly more complex and nonlinear modifications are likely necessary for improved accuracy (Veldkamp and van der Tempel 2005) particularly of joint wind and wave loading (Ditlevsen 2002; Tarp-Johanssen 2005). Further, uncertainty remains particularly regarding extreme wave loading in shallow water depths where the current generation of offshore turbines is deployed. As relatively high waves run into shallower water (Gravesen et al. 2005)(Christensen et al. 2007) (i.e., at about $H/d > 0.3$) the wave shape distorts (van der Temple 2009) and ultimately the wave will break (at approximately $H/d = 0.78$). The breaking wave load can be approximated using (van der Temple 2009):

$$F = \frac{\rho_w}{2} C_s A u_w \qquad [12]$$

where

A is the area exposed to the breaking wave

C_s is the slamming coefficient (approximate range 2–6.3)

Full treatment of combined wind–wave loading remains incomplete, but innovative solutions to reducing the probably of structural failure of offshore wind turbines due to wind and wave loading are being vigorously pursued and include tuned liquid column dampers (Colwell and Basu 2009) or modification of the support structure construction materials (van der Temple 2009).

WEC are potentially even more sensitive to possible changes in extreme wave conditions than wind turbines deployed offshore. Indeed, the two primary design and cost considerations for WEC are the need to generate energy at competitive economic rates in average sea states and the need for the WEC to ensure survivability in extreme storm (and wave) conditions (Westphalen et al. 2009; Van Paepegem et al. 2011). Given the importance of the overall cost of engineering the device to withstand extremes, over-engineering can render the WEC uncompetitive, while the converse can lead to catastrophic failure.

Sea ice and particularly drifting sea ice potentially greatly enhances wind turbine foundation loading and would also pose a substantial threat to wave energy devices. For example, the drift speed of ice floes can exceed 1 m s^{-1} in some parts of the Baltic Sea and can cause high loads and severe vibration problems on offshore structures (Karna and Kolari 2004; Barker et al. 2005; Gravesen et al. 2005). Ice cones (Yan et al. 2006) have been deployed on some turbines within this region to reduce the ice forces acting on the structure by a factor of 5–10 (Vølund 2005), though they do add to the size of the structure at water level, which may enhance wave loading. There is some evidence for historical decreases in ice cover in both the Baltic Sea and the Great Lakes and speculation for continuation of those tendencies in the future (Pryor and Barthelmie 2012a), though the implications for wind and wave energy extraction technologies remain somewhat unclear.

Icing on wind turbines derived from atmospheric deposition also represents a major challenge to installation and operation of wind turbines (Hochart et al. 2008) and even modest accumulation of ice substantially reduces electrical power production (Laakso et al. 2003; Dalili et al. 2009), although proven solutions to preventing and reducing icing exist (Hochart et al. 2008). Given the complexity of the processes involved in icing (Pryor and Barthelmie 2012b), the potential impact of climate nonstationarity on the frequency or intensity of icing in specific locations is uncertain.

3.04.4 Concluding Remarks

Tremendous energy is available in the form of winds, waves, and tidal currents, and technologies exist that allow electricity generation from the kinetic energy within these fluid motions. As described herein, the precise magnitude of the resources is variable dependent on assumptions regarding accessibility, and technological and societal constraints, but according to many assessments the technological feasible electricity generation potential may exceed current global demand. Of these resources offshore wind energy has greatest market penetration, but technologies to harness wave and tidal currents are proven.

Changes in local and regional climatology may change the context in which ocean energy technologies are deployed and operated. Herein we have presented a brief summary of the current status of efforts to harness these resources, and an analysis of the key parameters that exhibit both relevance to the renewable energy resources and potential climate change sensitivity. Changes in climate may alter either the resource magnitude or operating conditions for the ocean energy technologies, but research in these fields is relatively nascent. Research conducted to date has focused principally on offshore wind energy and indicates that at least in the regions that have experienced greatest deployment to date, climate change projections do not indicate substantial changes in the resource magnitude or loading conditions in the near-to-medium term.

3.05.1 Introduction

Biomass has been used as a fuel source ever since humanity learned to make fire. Biomass served as the primary source of energy—before fossil fuels became common in the twentieth century—and still remains the dominant source of energy for one billion of the poorest people (Nature News 2008). Biofuels are attractive for number of reasons. Plants act as 'solar panels' converting the incoming solar radiation to accessible energy, capture carbon dioxide from the atmosphere, and store energy.

Plants are considered inefficient 'solar panel' since they utilize only 1% of the sun's energy (Nature News 2008). The energy content of the biomass represents 95 TW constant energy flux (Miyamoto 1997). Energy is often discussed in energy amount terms expressed in J, ToE, or kWh with an implicit per year dimension which practically leads to energy flux; therefore, this chapter discusses energy uniformly as energy flux expressed in watts. Applying the 10% rule of ecology, which states that only 10% energy is transferred from one trophic level to another (and the remaining 90% is used to support the organisms' own metabolism), reduces further the biofuels' solar utilization efficiency (the ratio of the energy produced versus solar energy reaching the earth surface) to 0.1%. Furthermore, biofuel production (growing feedstocks, harvesting, and processing) adds an additional 'trophic level' that has its own 'metabolisms' taking up as much 66–90% of the energy produced. The energy requirement to produce biofuels are often characterized as the ratio (*r*) of the energy output–input. Optimistic estimates for r are in the 1.3–1.5 range (Giampietro et al. 1997; Shapouri et al. 2003). These ratios can be converted to the energy investment content as $\mathrm{Ce} = 1/r \ {*}100\%$ that yields $\mathrm{C^e} = 66.6-77\%$ which is remarkably similar to the ecosystems metabolism. Therefore, the resulting solar utilization efficiency intuitively could be as low as 0.01–0.03%.

Biofuels are still attractive because they solve the equally challenging problem of portable energy storage. Liquid fuels as portable energy have no real alternatives in many applications such as transportation, field equipments, etc. Interestingly early pioneers of automobiles Henry Ford and Rudolf C. K. Diesel saw biofuels as the fuel of the future.

In recent years, developed countries invested heavy in biofuels as a supplement to fossil fuels. For instance, the United States ramped up its biofuel productions. In 2007, 20% of the grains produced in the United States were used to make biofuels contributing less than 1% of the national fuel consumption (Pimentel 2009a). Unintended consequence of the increased biofuel productions was a rapid increase in food prices (Oxfam International 2008).

The climate vulnerability of biofuel productions is not any different from the vulnerabilities in food productions discussed extensively in other sections of this encyclopedia. A more fundamental question is, if biofuels could be considered as a major contributor to a decarbonized global economy.

3.05.2 Rationale for Biofuels

With the exception of geothermal energy, all renewable energy sources rely on the sun as the primary energy source, therefore they can be judged by considering their solar utilization efficiency. As a baseline to evaluate this efficiency, one should consider the ratio of the energy demand versus the available solar radiation. The Earth's surface (land and oceans combined) receives 95 PW solar energy (absorbs 89 PW and reflects 7 PW), but only ~30% is land, which receives ~27 PW (28%) solar insolation, since the average solar radiation hitting the Earth is slightly higher over ocean ($197\,\mathrm{W\,m^{-2}}$) than on land ($183\,\mathrm{W\,m^{-2}}$) (Jacobson and Delucchi 2011). Twenty-one percent of the continental land is not suitable for crop production; therefore, the solar utilization efficiency is around 0.45%, which already accounts for the plants metabolism. Hence the actual solar energy efficiency of the plants is 4.5%, which is much better than the 1% according to Nature News (2008).

It is also remarkable that the real solar utilization efficiency of the most efficient solar panels are very similar. Although 20–30% efficiency is reported for concentrated solar panels, but that is the efficiency of the panel itself, while the mirror reflecting the sun's radiation typically only covering 25% of the land. Photovoltaic panels (with up to 10% efficiency) when

http://dx.doi.org/10.1016/B978-0-12-384703-4.00312-9

installed with spacing are also likely to be under 5% solar utilization efficiency. Apparently, plants by no means are less efficient than solar panels. Based on the 0.45% theoretical solar utilization efficiency (after discounting for the plants metabolism), the net solar utilization efficiency is 0.045–0.15% (after adjusting for the energy demand of the biofuel production), which is somewhat better than our initial crude estimate (0.01–0.03%).

The solar energy available for biofuel production is less than the 79% that is suitable for biomass. Eleven percent of the continental land already used to grow crops and 9% is occupied by human infrastructures (Pimentel and Wilson 2004), that leaves only 59% of the land mass receiving ∼16 PW the solar energy available for energy production. The global energy use passed 16 TW in 2010 after a small drop for the first time in 2009, which is expected to grow (one has to note that all scientific papers (e.g., Pacala and Socolow 2004; Delucchi and Jacobson 2011) demonstrating possible pathways to decarbonized global economy that rely only on renewable sources (and exclude nuclear power) assume that global energy use can be lowered below contemporary levels and ignore more realistic IPCC energy demand projections anticipating substantial economic growth in the developing world) ∼28–60 TW (Grübler et al. 1996; Nakicenovic et al. 2000); therefore, the demand and solar power supply ratio today is ∼0.1% that will grow to 0.2–0.4%, which is far less plentiful than advocated and it is higher than the net solar utilization efficiency (0.045–0.15%) calculated above.

The low 95 TW energy available from biomass contrasted with the global energy use alone should be alarming, regarding the feasibility of biofuels as major source of energy, since it indicates that that a large share of the biomass will need to be utilized. At the 0.045–0.15% rate, biofuels could produce 7.2–24 TW net energy from the 16 PW reaching the available 59% of the continental land. Therefore, biofuels by no means could be or should be considered as a major source of renewable energy. The only reason biofuels might remain attractive is the recognition of the need for energy storage.

The energy density of fossil and biofuels exceeds the energy density of other viable means of storing energy, e.g., electric batteries, flywheels, pumped storage, etc. Furthermore, recharging batteries is slow compared to refueling. The slow recharging is not a technological challenge, but constrained by fundamental physics. The energy content of a 40 l fuel tank in a mid-sized passenger car is about 1320 MJ. To transfer that amount of energy in a 1–2 min refueling stop would require 220 kV at 50 A or 50 000 A at 220 V electric currents (i.e., the equivalent of the maximum electric load of 1000 homes using regular a 50 A circuit breaker). Even if electric vehicles take over some part of the ground transportation, battery powered aviation and other long distance transportation (that have no access to power lines continuously) seem to be infeasible.

Transportation takes up 20% (3 TW) of the global energy use today that varies by countries (e.g., 28% in the United States). Even if the energy demand to grow crops was satisfied from other sources (providing the 'metabolism' of the biofuel productions from external sources), producing transportation fuels from biomass for today's consumption would require the utilization of 3% of the continental plant biomass, which would need to double or triple.

These calculations are crude estimates that could have been made 20+ years ago. The following sections will be testing these rough estimation with real biofuel statistics and more comprehensive modeling studies.

3.05.3 Sources of Biofuels

Direct biomass combustion is the most efficient way of utilizing the plants energy that could be as high as 45% (IEA 2007), next to gasification of the solid biomass. Fuel shortage during World War II in Europe has led to the conversion of the majority of vehicles to firewood (http://www.lowtechmagazine.com/2010/01/wood-gas-cars.html) (Figure 1).

The gasification (burning the wood with low oxygen) has a 60–70% efficiency producing wood gas (a mix of hydrogen and carbon monoxide) that is combustible by both gasoline and diesel engines. Despite its relative efficiency, large scale adaptation of solid biomass as a transportation fuel is very unlikely and liquid or gas biofuels are likely to remain the preferred choice, unless other means of portable energy storage emerges.

Biofuels are normally characterized as conventional or first generation biofuels, second generation or cellulosic biofuels and next or third generation biofuels from algae. First generation biofuels only use some parts of the plants that contain sugar, starch or some form of oil that could be either fermented to some form of alcohol (e.g., ethanol) or converted to biodiesel. Second generation biofuels utilize the entire plant by breaking up cellulose to small sugar compounds that is ultimately fermented to alcohol. The next or third generation of biofuels is produced by algae under heavily controlled environment, where carbon dioxides are supplemented along with key nutrients.

3.05.3.1 Traditional Biofuels

The most efficient biofuels today are made from sugarcane. Sugarcane is a water intensive crop, which grows all year around in tropical climate. Brazil, the largest producer of ethanol, grows 73.8 t of sugarcane per hectare (Goldemberg 2008) that yields up to 9000 l ethanol (Brown (2006) gives a much more modest 2500 l ha^{-1} estimate that is below sugar beets). Considering the energy density of ethanol (24 MJ l^{-1}) and the solar radiation all year around, the solar utilization efficiency is 0.37% (less than our 0.45% rough estimate without adjusting for the energy needed to grow, harvest, and process the sugarcane to produce ethanol).

Sugarcane is by far the most efficient crop in terms of return on energy investment (Brown 2006). The 1:8 ratio (one unit of energy yielding eight times more energy) means that the production efficiency is 87.5% and only 12.5% energy is lost to support the production's 'metabolism.' Part of this high efficiency comes from using the rest of the sugarcane as solid fuel resource. Due to the high efficiency of the ethanol production from sugarcane, the net solar utilization efficiency is 0.315%, which is higher than the current energy use solar radiation ratio and will remain even in the future, with elevated energy demand.

The second most efficient biofuel crop is sugar beet, which could yield 2700 l ethanol per hectare (Brown 2006), that is

Bundesarchiv, Bild 183-V00670A
Foto: o.Ang. | 1946

Figure 1 Wood gas car from WWII era.

0.11% solar utilization efficiency one-fourth of our crude estimate. Sugar beet has 1.9 units of energy output for one unit investment (which is 47.3% production efficiency), so the net solar utilization efficiency is 0.051%, significantly below sugarcane. The relatively high production efficiency cancels out the lower than expected solar utilization efficiency; so the resulting net solar utilization efficiency is in the same ballpark as our crude estimate.

Corn ethanol is the third most efficient biofuel that yields 1350 l ethanol per hectare. The solar utilization efficiency therefore is 0.06% (significantly below our initial 0.45% estimate). The energy return of corn ethanol is heavily disputed. Some authors argued that the net energy return is either miniscule or negative after factoring in the energy cost of growing crops and processing into biofuel (Giampietro et al. 1997; Pimentel 2009b). Other authors demonstrated that the energy investment return ratio is positive and could be as high as 1.5 (Brown 2006). The more realistic consensus value is 1.25 (Hill et al. 2006; Farrell et al. 2006), which leads to 20% production efficiency. The dominant portion of the extra 25% comes from accounting for the energy content of the by-products, without that, the energy content of the produced ethanol and invested energy are almost the same (Hill et al. 2006). The net solar conversion efficiency is a very low 0.01% (below our initial 0.045% estimate).

Critiques, who defended corn as viable source of biofuel, apparently addressed the wrong side of the equation. Corn clearly passed the point where it can be considered as any energy source, but it may remain as a viable means of producing liquid fuel. At 0.06% solar conversion efficiency 18% of the continental lands (receiving 27 PW solar energy) would be needed to satisfy the 3 TW liquid fuel need of the transportation today.

Biodiesels represent another class of biofuels derived from oily plant products (e.g., palm oil, coconut, rapeseed, peanut, sunflower, and soybeans). Biodiesels have 38% higher energy content (33 MJ l^{-1}) than ethanol, but most of the plants producing them have lower yields. Only palm oil and coconut (which can only grow in the tropic) have comparable yields 1900 and 870 l ha^{-1}, respectively (Brown 2006). Those plants that grow in temperate climate have lower yields (Brown 2006) between 211 l ha^{-1} (soybean) and 380 l ha^{-1} (rapeseed) resulting in 0.05–0.10% solar utilization efficiency for tropical crops and 0.01–0.02% for temperate crops (well below our crude estimate). These are very low numbers, way below our crude 0.45% figure, regardless of the energy needed for producing them. While the energy investment return ratio of the soybeans are as high as 1.93 (Hill et al. 2006), it does not help in offsetting the poor overall solar energy conversion efficiency.

3.05.3.2 Second Generation Biofuels

Second generation biofuels convert cellulose to liquid fuel allowing the utilization of the entire plant that is made up dominantly by cellulose. Despite its appeal, cellulosic biofuels are still in the experimental stage and commercially viable solutions that are ready for large scale adaptation are anticipated to require another decade of research and development (Schnoor et al. 2008). The main challenge of the cellulosic biofuels is the efficiency of the cellulose conversion. While enzymes can convert sugar to ethanol with 90% efficiency, converting cellulose to ethanol has only 40% efficiency (Service 2010), because the cellulose needs to be broken up first. As a result, converting plant biomass to ethanol requires processing much larger amounts of feed stock to produce the same amount of biofuel than conventional biofuels. Temperate zone plant biomass per hectare could be as high as 20 t. Switchgrass have reported yields up to 30 t ha^{-1}. The most efficient cellulose conversion yields 180 l ethanol from 1 t of feed stock (Badger 2002) resulting in 3600–5400 l ha^{-1}, that would represent 0.31% solar utilization efficiency. The 180 l t^{-1} might be an optimistic productivity that largely depends on the efficiency of the cellulose to sugar conversion that could be as low as 76 l t^{-1} and has a theoretical limit at 350 l t^{-1} (Badger 2002). If truly realized, the 0.31% solar utilization efficiency would approach sugarcane.

Melillo et al. (2009) arrived at a similar 0.26% solar utilization efficiency modeling the production of 10.2–11.6 TW energy (anticipated to cover the energy needs for transportation by 2100) over 14–15% (20.6–21.6×10^6 km^2) of the continental land with a Terrestrial Ecosystem Model (Melillo et al. 1993). While the authors of this study discuss the impact of such land use change on carbon emission, they do not mention the consequences of appropriating additional 14–15% land for biofuel production (without actual energy gain).

One has to recognize that the 0.31% solar utilization efficiency is largely an optimistic estimate that is not yet supported by real world data. Commercially operational systems are still lagging, because conventional biofuels are still less expensive to meet the government dictated biofuel contribution (Service 2010). It is certainly alarming that cost competitiveness of the cellulosic biofuels remains behind traditional biofuels.

3.05.3.3 Third Generation Biofuels

A third class of the traditional biofuels (besides ethanol and biodiesels from terrestrial plant) is the biodiesel from algae. Microalgae is largely promoted as the truly viable means of biofuel production. Interestingly, the literature discussing terrestrial crops are rather quiet about the production rates per unit area, while the microalgae literature emphasizes heavily the much improved land use efficiency. The reported 98 400 l ha^{-1}

bio-diesels yield (Chisti 2008) is indeed impressive and represents a remarkable 5.4% solar utilization efficiency. At this level, plants are comparable to solar panels. If realized, microalgae could compete not only as liquid fuel, but as an energy source with regular solar panels.

While the theoretical yields of microalgae are indeed promising, the reality is that these yields could be achieved only in the tropics and subtropics and require significant infrastructure. The open pond systems have far less efficiency and the high yields are achieved only in 'closed' system, where the microalgae grown on plastic tubes constantly feed with CO_2 and various nutrients, while the produced O_2 is degassed regularly. These facilities are more akin to incubators than agricultural fields, and the high solar utilization efficiency comes from significantly reducing the energy needs of the microalgae to maintain their own metabolism. In other words, the microalgae are spoon fed to the degree that almost all of the energy they consume goes into producing biomass.

3.05.4 Biofuels and Climate

Growing feed stocks for biofuel productions has similar climate vulnerabilities and impacts on the climate system as food production. The primary difference is the degree to which intensive agricultural practices, that tend to need more energy, can be applied for energy crops. In other words, if the additional energy invested in the crop production can be justified in terms of the energy return from growing more crops.

Given the poor solar utilization efficiency of biofuels demonstrated in the previous section, satisfying liquid fuel demands via biofuels will require substantial land conversion. Growing plants for biofuel will inevitably lead to competition with either food production or ecosystem preservations. Proponents of cellulosic biofuels often emphasize that the feeds stock to produce cellulose can be grown on marginal lands that are not suitable for food crops, but they forget to realize that those 'marginal' lands are often the last sanctuaries for wildlife.

3.05.4.1 Climate Impacts

Land cover conversions affect the climate a number of ways. The change in albedo alters the energy budget, while the changes in the plants' physiology and phenology modify the water budget. Plant characteristics (e.g., canopy height, rooting depth, leaf area index, etc.) affect land surface properties. The climate impact depends on vegetation that is replaced and the plants that are grown instead (Pielke et al., 2007). Land conversion from forest or tall grass to annual crops is reported to increase albedo and decrease water uptake, while replacing short grass could decrease albedo particularly outside of the growing season (Beltrán-Przekurat et al. 2011).

Land conversion to expand first generation biofuels productions will have the same climate impacts as traditional food crops, since their feed stock comes from similar plants. Second generation biofuels utilizing plants that are closer to native vegetation will lead to a return to land-cover conditions closer to natural conditions. Georgescu et al. (2011) analyzed the impact of converting annual crops to perennial switchgrass in the United States and concluded that such conversion would lead to a regional cooling, due to increased evaporations combined with higher albedo throughout the entire year, which is just the opposite that occurred when tall grass vegetation was converted into croplands.

Land conversion for biofuel production can increase greenhouse gas emission (Searchinger et al. 2008) through emission due to land-use change. Melillo et al. (2009) argued that proper agricultural practices (particularly in terms of sensible fertilizer use) combined with protecting forested lands could reduce greenhouse gas emissions dramatically.

3.05.4.2 Climate Vulnerabilities

First generation biofuels likely have the similar climate vulnerabilities to traditional food crops, since they are not fundamentally different. If second generation biofuels will ever become a reality, their feed stocks will likely be more resilient for several reasons. Firstly, second generation biofuel crops will be closer to natural vegetation that adopted to particular climate conditions (e.g., switchgrass or managed forests). They have demonstrated resiliency surviving in marginal lands. These perennial plants will grow continuously, as the weather conditions permit, without elevated sensitivities during particular phases of their phenology (e.g., early plant growth or around harvesting) as a consequence, harvesting could be aligned better to periods when the harvesting is convenient, as opposed to being dictated by the crops' maturity.

3.05.5 Summary

The solar utilization efficiency of the biomass is clearly below the ratio of energy demand and the available solar energy, which by itself should have ruled out biofuels as viable renewable energy source. With the exception of sugarcane and microalgae (if it becomes scalable reality), biofuels are not efficient enough to become major sources of energy. Various forms of biomass should be utilized whenever they are available as a supplemental energy source, but plants are not efficient enough to capture solar energy.

The only rational for biofuels is if there is no alternative to produce similar portable form of energy. Even if the energy to produce biofuels is produced elsewhere, and biofuel only serves to provide liquid fuels, the land requirements are still huge. While satisfying liquid fuel demands using biofuels is possible, the environmental costs and competition with other land uses (particularly food production) probably will be prohibitive.

Sacrificing 14+% of land just to produce biofuel (while the actual energy still needs to be produced elsewhere) will clearly introduce competition for land. Biofuel advocates are very keen in claiming that their feed stock will not compete with food production, but the reality is, the 14+% expansion will either come from lands that could grow food or lands that was left for natural ecosystems. Lands dedicated to biofuel feed stocks are not likely to allow rich biodiversity, particularly the frequently disturbed monocultures. Managed forests might offer better compromise between biofuel production, while allowing healthy ecosystems to thrive for a decade or two between harvesting.

Perhaps, part of the reason why the high land requirement was not admitted as a major obstacle is that using 14+% of the land is not impossible, but clearly destructive either to food production or to natural ecosystems. It is hard to understand why renowned Nobel Prize laureate economist, Paul Krugman, is more willing to blame the weather (http://krugman.blogs.nytimes.com/2011/02/05/soaring-food-prices) for the soaring food prices than recognizing the obvious causality between the cost of food and burning food crops for use in gasoline.

If all the corn produced in the United States were diverted for ethanol production, it would only contribute 12% to its demand (Hill et al. 2006). In a world, where every seventh (925 million) person is still hungry (FAO 2010), burning food crops to substitute for a tiny fraction of the fuel demand is unethical. From the taxpayers perspectives, donating subsidized agricultural products to feed the hungry would have just as little or no benefit as burning it in cars, but at least it would support a noble cause.

3.06.1 Introduction

An economy based on solar energy has been the dream of many for many years. It would be great to depend only on the freely distributed energy of the sun, which is available everywhere. Doing so might diminish geopolitical concerns and environmental impacts. However, the current reality is quite different. While energy from the Sun is free, it is very difficult to collect it, concentrate it, convert it, move it, and store it. You could say that nature has developed a great way to accomplish these tasks for us – converting the products of biological photosynthesis into oil and concentrating it in geologic reservoirs in a liquid form with high-energy content that allows easy transport and storage. However, that process required millions of years to build up resources we are using up at an increasing rate; it would be nice to develop our own way of accomplishing this in a way that is economically and environmentally feasible.

This chapter first looks at the important role that energy plays in society. It has been one of the main drivers in the organization of civilization and, before that, in evolution. The availability of relatively inexpensive energy could solve many other problems, for example supplying fresh water through desalination.

While solar energy might include a wide range of potential energy sources, including the previously trapped solar energy in fossil fuels, the indirect renewable solar energy of wind and waves, and the natural direct way of growing biofuels, the solar energy considered here is restricted to solar concentrators, solar photovoltaics (PVs), and artificial solar chemical processes. After we consider these, we explore both the related uncertainties and the possible range of climate variability. Then characteristics of the various technologies, uncertainties, and potential climate effects are identified. An analysis explores the solar energy technologies, uncertainties, and vulnerabilities related to climate.

Finally, an integrated analysis method of real options analysis (ROA) provides a potential semiquantitative framework for discussion and interpretation. The purpose of this chapter is not to address the potential impact of using these renewable resources on the consequences or probability of climate variability; this has already been addressed in a wide variety of reports (IPCC 2011).

3.06.2 Energy Is Key

Previous studies have suggested that technology, energy, and societal changes are coupled, perhaps in a long-term learning pattern (Marchetti 1980; LePoire 2010a). Major changes in energy sources and in the intensity of energy use in this sequence seem to coincide with some transitions in international leadership (i.e., when a nation-state overtakes a previous leader). The current struggle to supply expanding energy demands to a global economy will also be likely to use new technologies, such as nanotechnology, biotechnology, information technology, and cognitive science (NBIC) for new energy sources, conversion, storage, and transmission (Roco and Bainbridge 2002). While the United States currently leads the way in the development of many high-level technologies, other countries, such as China, are indicating their interest in these technologies through their internal research and development (R&D) investments (Lacey 2011). The use of new technologies in energy production is important to understanding leadership transitions, since it has been suggested that a major factor determining whether societies transform to more complex forms is their ability to increase the intensity of energy use. To gain a wider perspective, the historic roles of energy, technological, and leadership development are reviewed within a possible logistic growth and transition framework.

White (1959) was one of the first to make the connection between energy and cultural change. He identified the leverage that technology could provide to sustain more complex societies. This work was incorporated into the analysis of the collapse of complex agricultural societies by Tainter (1988, 1996), who identified the marginal return on investment of resources, such as energy, as societies grow larger and more complex. He

http://dx.doi.org/10.1016/B978-0-12-384703-4.00309-9

suggested that many agricultural societies collapsed because they overextended their reach into nonsustainable systems. The impact of environmental degradation has also been an important factor in the development and decline of civilizations (Ponting 2007; Chase-Dunn and Hall 1997; Diamond 2005). Most analyses focused on agricultural societies because of their simplicity relative to industrialized societies.

Chaisson (2001, 2004) recently connected the flow of energy (i.e., the free energy density flow) to possible bifurcation points throughout the history of the universe, from galaxy formation to present society. However, Chaisson's focus was on connecting the early development of galaxies, stars, and planets to the period of time since the Big Bang. Therefore, graphs of the progression of energy flow over time display recent acceleration.

A slightly different point of view is obtained if energy use comparisons are made based on times before the present. They show a geometric increase in energy use through biological, cultural, and technological evolution with logarithmic time (LePoire 2010b). The connection between increased energy flow and historical transitions was also suggested by Prigogine (2000) and Spier (2010).

Richard Smalley of Rice University, the 1996 Nobel Prize winner in chemistry for the discovery of fullerenes in the mid-1980s, offered a possible way to tie these transitions together and hopefully take advantage of their benefits while managing, or at least reducing, possible risks. He suggested that the United States should lead an international effort to explore the possibilities of using nanotechnology in the energy sector. He argued that energy is the key to many international problems, such as the water crisis, food availability, environmental deterioration, poverty, terrorism and war, disease, education, democracy, and population sustainability (Smalley 2003).

How might nanotechnology be applied to the energy problem? Smalley identifies a set of technologies, from cheaper and more efficient production of PVs to dye-sensitized coated nanoparticles forming Graetzel cells. Storage and transmission issues can also be addressed with technologies that facilitate photoconversion of water to hydrogen, better fuel cells, better hydrogen storage, and more efficient power cables. Additional resources facilitate new research communication, linking ideas with market opportunities, and comparison of global strategies. The U.S. Department of Energy shares research discoveries of the Advanced Research Projects Agency – Energy (ARPA – E) through conferences (U.S. Department of Energy 2011a) and energy innovation portals (http://techportal.eere.energy.gov) with webinars.

Another model of technological progression and diffusion is based on the logistic equation. This progression assumes that the rate of progress is proportional to both the current level of complexity and the fraction of complexity yet to be discovered. Modis (2002) suggests that the history of the universe might best be viewed as a logistic development of complexity. He arranged important events in the history of the universe from a variety of sources, assumed that each event was equally important, and then made the assumption that the complexity of an event is its importance divided by the transition time to the next event. The dependence of the cumulative fraction of complexity on milestone number (not the event's time) could be interpreted either as the first half of a logistic curve or a sequence of events that will culminate in a singularity. A logistical development of complexity would mean that the rate of development depends on the product of the cumulative complexity of previous events and the fraction of complexity is yet to be discovered. Modis favored the logistical development interpretation.

Logistical trends in the world's mix of primary energy sources were observed (Marchetti 1977) in the mid-1970s. The analysis was based on an extension of the Fisher–Pry (Fisher and Pry 1970) model for substitution. The model accounted for the shifts in primary energy use from the early 1700s, where wood was the primary source of energy, through the 1800s, where coal use climbed, through the early part of the twentieth century, where oil became predominant and uses of natural gas and nuclear power rose. The logistical trends were extended to predict the fall of the fraction of energy from coal, the peak in the fractional use of oil, and the continued rise of both natural gas and nuclear power in the 1990s.

However, the actual use of primary energy sources during this period has shown deviations from these predictions, in that the relative fractions of the primary energy sources seem to have been somewhat stable since 1990 (Kulcinski 2004). During this period, total energy demand substantially rose, but the contributions from each primary energy source kept pace. While it was recently suggested (Smil 2000) that the logistical analysis of primary energy sources might not be appropriate for predicting long-term energy use, perhaps an extended substitution model including efficiency could help explain these trends. A large factor in energy use dynamics in this recent period was substitution of conservation and efficiency for actual use (Ausubel 1996). A simple measure of the world's energy efficiency over this period can be constructed based on energy intensity (i.e., the measure of gross national product per unit of energy use) and incorporated into the logistical model. With this extension, the logistical model is more consistent with historical data, including the current trends (LePoire 2004) (Figure 1). This suggests that energy efficiency (or conservation) might be viewed as a viable alternative when considering energy use. Some see the possibility of greater efficiency in energy use (Ayres et al. 2007). If the 'efficiency' wave follows a substitution path similar to that of coal and fluid fossil fuels (oil and natural gas), a new wave would be expected to follow. The transitions to alternative energies have come in slower discrete steps, first through the development of hydropower dams, then through nuclear power. If alternative energy sources continue to follow the efficiency wave, they are expected to be comparable to the energy derived from fossil fuels after 2050.

3.06.3 Energy Scope

The amount of solar energy absorbed by the Earth is large compared to the current consumption of energy. The amount of energy absorbed in 1 h is equivalent to the annual total energy used around the world. A small fraction of this energy is converted into wind (0.06%) and slightly more is converted by photosynthesis into biomass (0.077%). The amount of solar energy absorbed by the Earth in only half a year would

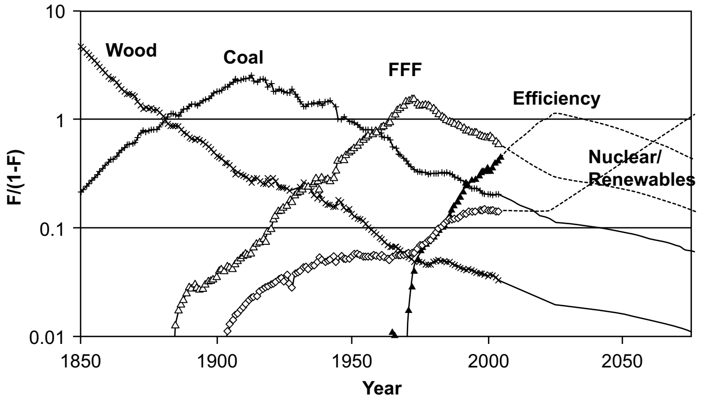

Figure 1 Logistical trends of world energy use extended in time with projected data from the International Energy Outlook of the U.S. Department of Energy's Energy Information Administration. The *y* axis shows the ratio of the fraction (F) from a fuel source to the fraction (1-F) from other sources. The transitions follow from wood, coal, fluid fossil fuels (FFF, i.e., oil and natural gas), efficiency, and then a growing fraction of nuclear and renewables. The historical analysis includes the energy saved through efficiency (and conservation) as measured by considering the energy use to gross domestic product (GDP) ratio. The projections are based on continued logistical substitution.

be equivalent to the total amount of nonrenewable energy that exists in the form of fossil fuels and uranium.

This chapter covers PVs, concentrating on thermal solar power and engineered chemical conversion. It does not include biofuel production, even though distinguishing between these may become increasingly difficult as natural biological and engineered systems are merged (e.g., genetic engineering of plants and use of algae in process systems). We do not consider indirect solar energy such as the conversion of heat differences into wind and waves. Another type of indirect solar energy is generated by hydropower dams, which rely on the sun evaporating water for later collection at higher altitudes. Large-scale hydropower energy generation is quite efficient and has limited environmental impacts near the dam; however, many of these locations have already been developed, leaving limited growth opportunities for smaller installations. Solar heating of housing spaces and water is very important but is considered part of energy efficiency in building design. Classification by passive, active, and indirect technologies is shown in Figure 2. This is just suggestive because the boundaries between these categories are often blurred.

Solar energy depends on infrastructure, most specifically on that related to the transmission and storage of energy. If the requirements are not met, for example if solar energy is only

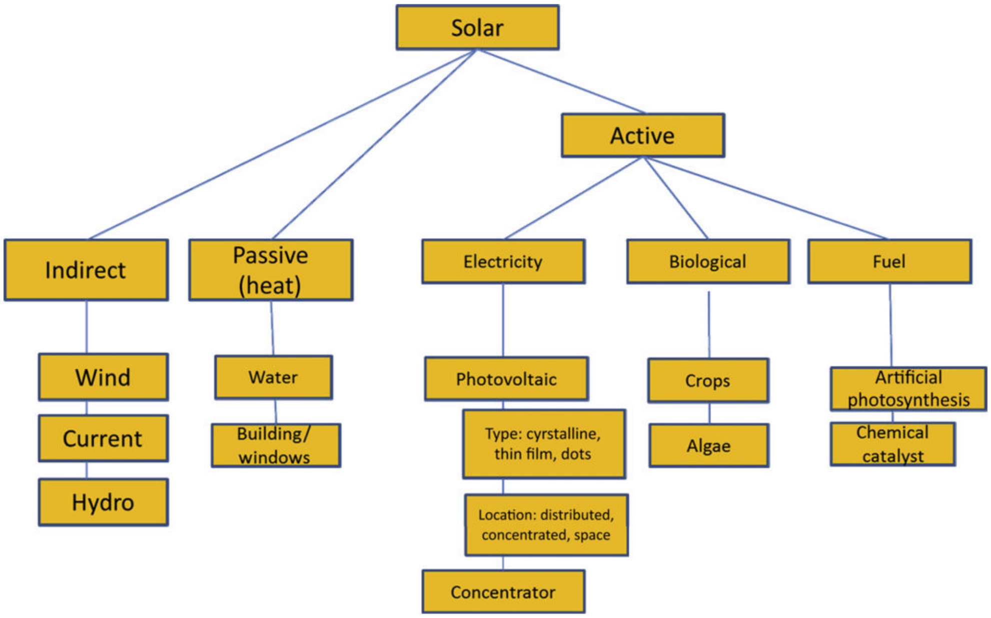

Figure 2 Organization of some solar energy sources by passive (e.g., buildings, water heaters), indirect (wind, current, hydropower, and ocean thermal), or active. The active part includes growing biofuels. More emphasis in this analysis is given to active generation of electricity or catalyzed fuel. Electricity can be generated through solar concentrators using heat engines or the use of PVs.

available during clear sunny days, then requirements for supplemental energy production (e.g., gas turbines) are needed. Integration into the grid may require long transmission lines and better pricing (smart grids) (Solar 2011).

Techcast (Halal 2008; Halal and Huhn 2012) polls experts about the future prospects of technological development. The current poll on alternative energies, including nuclear and renewables (biomass, hydropower, wind, and solar), suggests that 30% of energy will be globally supplied by alternative energies in 2023 (±5 years). This is somewhat in line with the projections of various governmental agencies, such as the U.S. Department of Energy (DOE) projection of 28% by 2036, the California and Hawaii goals of 20% by 2020, and the European Union goal of 22% by 2020. Currently, about 18% of energy is globally supplied by alternative energies (i.e., 82% of energy is fossil based). This includes the 6% nuclear and 12% renewable, the latter of which is dominated by hydropower (6%) and biomass (4%) such as wood. Only 2% comes from wind and solar energy, and the majority of that is wind energy. However, the growth rate for solar energy has been spectacular (although it started from a very small value), growing by about 60% per year from 2006 to 2011 (i.e., a factor of 10 in this time frame). However, in 2011 there was an oversupply of solar panels, resulting in a projection of only about 10% growth in the next few years. The cost of solar panels dropped from about \$1.75 W^{-1} to about \$1.10 in 2011. This panel cost is usually only about half of the installed cost; the rest of the cost comes from power electronics (10%) and installation, along with balance-of-system costs (40%).

A recent exploration of possible scenarios was conducted (Lovins and the Rocky Mountain Institute 2011). These scenarios included business as usual, a slow migration to alternative energies, and a transformation of the energy sector through breakthrough efficiency and renewable development.

The DOE Sunshot Initiative has been promoting a goal of less than \$1 W^{-1} of installed capacity by 2017 (U.S. Department of Energy 2010). It looks at the three potential candidates for solar PV: crystalline silicon, thin film, and concentrated PVs. A recent workshop identified the potential costs savings leading to this goal. A major target is the expense of installing the panels. The panels must be protected from the worst types of weather, so designs incorporating different material and inexpensive shock absorbers are being studied. This is crucial for considering the effect of potentially more violent storms in areas where the panels might be installed. Further exploration is being conducted to reduce the thermal response to the system and improve efficiency, installation costs, and overall lifetime.

Each solar technology has environmental impacts (U.S. Department of Energy 2011b). A common impact is the use of a large area, although the area might already be in use (roofs) or in remote locations (deserts). Production material impacts vary among the technologies, including glass and polymer for concentrators, semiconductors for light conversion, rare earth elements for the transparent layer of PVs, and a host of catalysts for chemical conversion. Operating material impacts include the water requirements for operating thermal engines or for keeping the surfaces clean. Further resources are needed for transmission, storage, and base-load backup. Another measure of impact is the energy return on investment, measuring the energy required to make, operate, and dispose of the energy producer over its lifetime. These measures of material and energy use are often captured in a lifecycle analysis.

Total lifecycle costs are needed to identify the main determinants of lifetime, maintenance, and improvements to extend life. This is especially true for solar because the fuel is free and the main cost is the initial capital cost. Extended over the lifetime, these costs really determine whether solar energy is cost effective or not (Humphries 2011). Besides total lifecycle costs of the specific installation, solar technology and its commercialized production is still rapidly developing. There are many uncertainties and potential paths yet to be explored that will determine the final portfolio of potential options, such as land requirements, integration into the electricity grid, resource requirements, and overall costs.

A major resource requirement for capturing the diffuse energy of sunlight is the land on which to place the solar collectors. Location depends on the availability of good sunlight, good connection to the grid, and sufficient land, as well as being able to easily construct and maintain the facilities. Various locations include distributed houses and business rooftops (German), deserts, oceans, Earth orbits, and the moon. The Energy Realities Web site offers many information resources, including a map of solar irradiance. Many of the world's deserts can be identified with the highest irradiance (**Figure 3**).

A summary of some solar technologies including a short description, current use, possible projection, and examples of research and development actions is listed in **Table 1**. The concentrator and PV are still being researched, but large-scale deployments are also being made, so these technologies are more mature and known. The artificial photosynthesis technology is newer and has not been commercially deployed, but it aims for a market which others have difficulty filling (i.e., production of high-energy density fuels for transportation).

An alternative to using fuels for transportation would be to convert transportation systems to run on electricity or convert electricity to fuels for use in transportation. However, these would require larger investments in infrastructure to support them. Since there is already an infrastructure for liquid fuels, the more direct production would facilitate conversion of transportation to solar power. A brief description of this artificial photosynthesis research follows. Two longer-term extensions of PVs are the ability to collect a broader range of frequencies and to overcome the limiting day–night cycle of terrestrial installations. These two extensions are also briefly summarized.

Biomimicry was employed in Nocera's 25-year quest for scalable solar energy solutions (Nocera 2009). In their search for creating artificial photosynthesis, his team at Massachusetts Institute of Technology recently identified two natural biological techniques that had previously remained hidden. He noticed that some life forms use cobalt in photosynthesis. He then developed a long-lived cobalt-based catalyst that uses sunlight to convert water into oxygen and hydrogen gas. This work supports his goal of finding a chemical process that could be distributed (e.g., on houses) and robust (e.g., not decay) in converting sunlight into liquid chemicals (e.g., alcohols) that store energy for later use in transportation as a gasoline substitute, or as electricity with a fuel cell. His team's recent discoveries have led to a start-up company, Sun Catalytix, that is partially funded by the US government's ARPA – E program, which funds selected promising energy-related innovations. Figure 3 Web sites such as Energy Realities offer information resources regarding the energy situation and opportunities. This particular snapshot shows solar energy potential based on solar irradiance. Many of the world's deserts show up tinted orange. The sparcity of sunlight in Canada, northern Europe, and Russia is visible. [Available online at http://www.energyrealities.org/our-resources/solar-and-wind-energy-potential/erp64A8DF68B7E76DA07.]

the lab, it seems like the catalyst also works in impure water, which could lead to it being used not only to generate and store solar energy but also to purify water. Lewis at Caltech is also searching for artificial photosynthesis in a different way, by using nanotubes along with a membrane to generate hydrogen from light (Lewis 2012).

The use of nanotechnology might lead to designs that more efficiently convert energy. Two examples can be found in the fields of solar and nuclear energy. In the solar area, conventional solar cells use silicon cells doped with special elements. Visible light strikes a cell, causing an electron to jump into a conducting zone. The electrons are then collected as electricity. The interaction of light with the electrons might not be efficient as a result of other energy transfer mechanisms, such as the light creating heat or the electron losing the energy before contributing to the current.

However, sunlight includes more than just the light we see. Much of the energy from the sun is infrared light that we cannot directly see but we can experience as heat. Infrared light is also generated when the visible light from the sun heats the earth. This energy can be reradiated into the sky, contributing to the cooler, clear, cloudless nights. A solar cell that could extract this infrared energy would be able to provide energy both day and night (although not as much at night). However, the infrared light does not have enough energy to kick the electrons to their conduction zone.

Another way to extract energy from the light is to use an antenna, much like a radio or cell phone antenna (Stricker). This method of collecting solar energy has advantages, in that an antenna is more efficient at capturing the energy, absorbs at a wider range of angles than conventional cells, and does not require exotic materials to make. However, the antenna has to be about the same size as the wavelength of the light. For radios, this is about 1 m. For cell phones, it is a few inches. For short-wavelength infrared light, the wavelength is about 1/25 of the width of a human hair.

One antenna would not only be difficult enough to make, but it would also result in very little energy production. The challenge was to easily produce millions of these small antennas, which was successfully done at Idaho National Laboratory (a DOE facility) along with other laboratories; the work received the 2007 Nano50 award. The laboratories were able to 'print' 250 million metal antennas on plastic about the size of a standard sheet of paper. However, converting the absorbed energy (10 GHz frequency) into useful electricity (60 Hz frequency) remains a problem. This conversion typically requires the use of diodes that allow the flow of electricity in only one direction. The University of Colorado at Boulder is currently making progress in developing the necessary diodes.

The idea of solar space-based energy extraction has been around for decades. Obstacles include the high price of sending reliable equipment into space, maintaining it there, and the

Table 1 Brief summaries of some solar power technologies. Organization into direct and indirect capture is shown in **Figure 1**. Characteristics include a brief description, current and possible projections, and example R&D actions

Solar energy technology	*Brief description*	*Current and projected use*	*Example R&D actions*
Solar thermal water heating	Mostly distributed residential and commercial installations to heat and store water for local use	154 GW China (plan on 210 GW by 2020), true potential scenario (420 GW by 2015), and 1500 GW by 2050)	Reducing cost and extending ease of connection
Concentrated solar	Mirrors focus light onto a centralized tower; parabolic troughs focus on a tube; or dishes that have a central focus on Stirling engine	1 GW (2010), 1.5 GW (under construction), 6 GW (contracted); Spain, United States, Algeria (Desertec (Hickman 2011))	Reduce cost of mirror, replace glass with polymer, increase efficiency, mass production
Photovoltaic	Doped semiconductor, either in crystalline or in thin film form; solar light energizes electrons to conduct electricity; some systems enhance collection with concentrating lenses	Capacity of over 60 GW by the end of 2011 Lovins (Lovins and the Rocky Mountain Institute 2011) 2050 scenarios (in units of installed capacity/% of electrical energy use): ● Maintain: 200 GW/10% ● Renew: 500 GW/30% ● Transform: 1000 GW/40% Most in the form of utility-scale plants	Use of quantum dots or multilayer films to capture a broader set of wavelengths; some materials require rare earth elements (Humphries 2011); some materials are environmentally hazardous and might be released during production or after use, but this could be mitigated by developing a recycling initiative (Knight 2010)
Solar chemical	Captures solar light with molecules and converts the energy into chemical bonds; sometimes similar to artificial photosynthesis; a large advantage is that liquid fuel potentially could be generated for transportation; the fuel also acts as a high-energy-density storage medium	Currently only research projects	Mimic nature with the use of cobalt-based compounds; take advantage of catalysis such as found in complex nanostructure materials
Biofuels	Crops are grown and converted to a liquid fuel such as diesel or ethanol; a disadvantage is the large amount of energy input required to grow the crops with fertilizers, transportation, and conversion; another drawback is the economic competition of the crops for both fuel and energy	Lovins (Lovins and the Rocky Mountain Institute 2011) 2050 scenarios (in units of % of electrical energy use): ● Maintain: 3% level ● Renew: increase to about 20% by 2030 while solar grows and replaces ● Transform: 6% peak	Ability to convert inedible parts of plants such as cellulose; ability to convert parts of inedible crops that grow on land that do not compete with food crops; decrease the cost to convert the crop mass into fuel
Hydropower	Elevated water from solar evaporation to drive turbines near a dam; most large dam sites have already been developed but some smaller sites remain; currently one of the largest (and oldest) of the renewable energy sources	Currently about 6% of energy Not much change is expected	Optimize energy extraction from rivers with minimal ecological disruption
Wind	Wind turbines generate electricity; the wind is generated by thermal spatial differences	Lovins (Lovins and the Rocky Mountain Institute 2011) 2050 scenarios (in units of installed capacity/% of electrical energy use): ● Maintain: 200 GW/8% ● Renew: 500 GW/30% ● Transform: 1000 GW/40%	Ability to connect into the grid; determination of lifetime costs; feasibility of offshore windfarms
Passive Buildings	Orientation, active screening, and thermal masses optimize the use of passive solar irradiation	Lovins (Lovins and the Rocky Mountain Institute 2011) estimates that in 2050 buildings might use half the energy, but this includes all forms of smart controls and efficient technologies, not just passive solar	Design integrated systems; use new materials and smart controllers to gain advantage

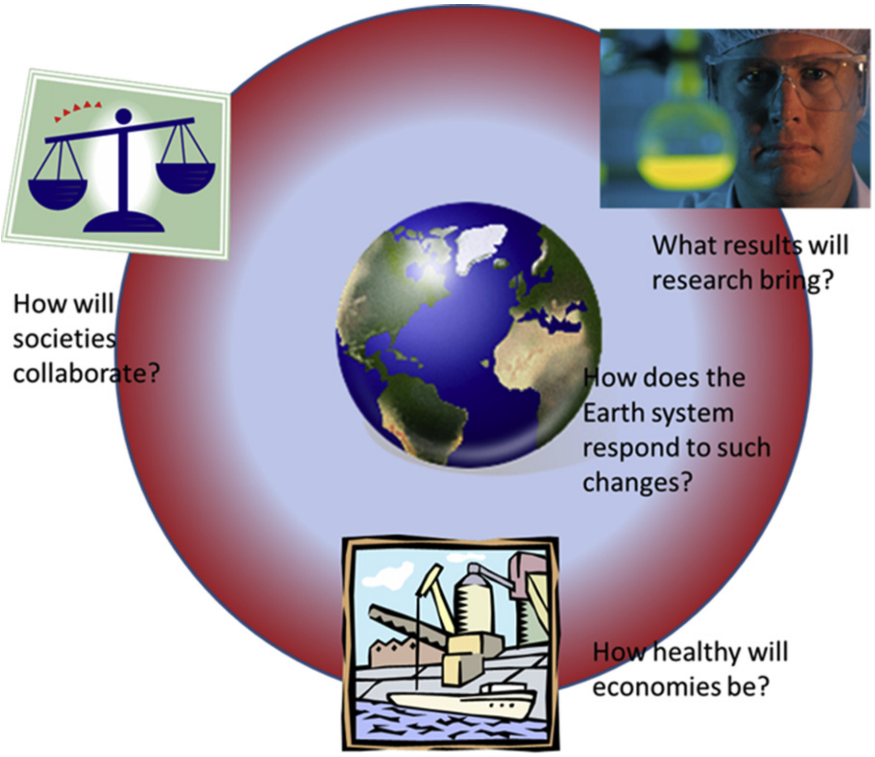
uncertainties associated with transmitting the energy back to the Earth (Landis 1990; Rouge 2007). Two locations are currently being explored. One is a geosynchronous orbit location. Satellites with very large solar collection arrays could be placed in geosynchronous orbit to continually collect energy from the sun at a fixed location above the Earth's equator. The benefits of this location include the lack of clouds or night interruptions and the fact that there is no need for a wide expanse of land for collecting the energy. However, the power must be collected and sent back to Earth. The original designs included microwave transmission from the satellites to an Earth-based rectenna. This system could reliably and efficiently transmit the energy to Earth, where it would be converted back to electricity and placed on the grid. In the 1970s, estimates for the system were made and compared with data on other technologies. At the time, the cost was found to be prohibitive. Japan is currently making an investment to look into this technology's near-term development (Richard 2009).

The other space location being explored is the moon, which offers the advantages of allowing the use of existing materials and providing a more conventional work environment. The available materials would, of course, have to undergo extensive processing to support the energy collection, electrical conduction, and conversion needed for microwave transmission. This would take quite a bit of effort, and current human space flight and work is expensive and difficult. A Japanese company (Corporation) is exploring the use of semiautonomous robots to do the primary conversion of materials and build the solar energy collection system. The idea is to create a continuous strip of land, perhaps going all the way around the moon's equator, of solar cell collectors built with moon materials. A complete equatorial ring would allow continuous energy collection. The sun shines only half the time on the far side of the moon, yet the same side of the moon is always facing the Earth, so just a limited number of transmitters would be needed.

To make this plan more feasible, space travel and the movement of materials need to be more economical. There have been several attempts to improve the space elevator concept, which was first proposed by the Russian scientist Tsiolkovsky in 1895 (Edwards and Bradley 2003; NOVA 2007). A major obstacle is the strength of the material needed for the spine of the elevator, which must reach over 24 000 miles from the geosynchronous orbit down to near the Earth level. Recently, the National Aeronautics and Space Administration (NASA) and Edwards have been updating the design on the basis of the idea that carbon nanotubes, which have the necessary strength, can be scaled up to provide enough material and consistency for the long cable.

3.06.4 Uncertainty Scope

There are different types of uncertainties (Figure 4). Many deal with the unknowns of the future (i.e., the results of research, the political responses, and the world economic situation). These future states of technology, political will, and economics are



How will societies collaborate?
What results will research bring?
How does the Earth system respond to such changes?
How healthy will economies be?

Figure 4 Sources of uncertainty in this issue. A central issue is our incomplete understanding of how the Earth system works, including the atmosphere, oceans, and ecosystems. Understanding this would help determine the relative costs of energy impacts and assess the potential limitations on development. Three issues shown on the outer rim signify uncertainty about the future: the results of research, the response of societies and states, and the state of the economy. These are major factors in determining costs and feasibilities of energy deployment.

embedded in a world that is facing many environmental limitations (Fiksel 2010). One response is to explore sustainable paths with renewable energies. However, this transition would take place within the context of other difficult transitions such as changing demographics, population pressures, and diffusion of technologies. One goal is to navigate these issues to a path that increases a sustainable quality of life around the world. A series of questions concerning uncertainties is presented in Table 2.

One uncertainty that is not tied to the future is exactly how the earth system would respond to various activities by humans. The environment system is not understood well enough to predict the results of atmospheric emissions or land development. This uncertainty is being tackled by improving models, collecting and interpreting measurements, and developing analogies. One difficulty in understanding such a complex system is its ability to support a wide variety of positive and negative feedback loops. Positive feedback (e.g., loss of reflective ice through warming causing additional heating through absorption) can result in nonlinear responses and discrete, perhaps irreversible, shifts to other system states. Some analogies that have been developed are often controversial and sometimes conflicting, such as the Panarchy (Gunderson and Holling 2002) model initially derived for isolated ecosystems, the Gaia Hypothesis (Lovelock 2006) that explores ways the Earth establishes a dynamic equilibrium, and the Medea Hypothesis (Ward 2009) that explores how the Earth system seemed to crash causing mass extinctions of life forms.

The social and political response uncertainties include the ability to collectively make decisions, the ability to finance large operations, and the incentives given to make changes. These tough problems, labeled as wicked problems by Conklin (2006), have characteristics that include a larger number of stakeholders or groups, goals irreducible to simple monetary measurements, large amounts of uncertainty, and potential nonlinearity, which makes them difficult to predict. The process of handling them requires decision under uncertainty with conflicting perspectives and interpretation, and the ability to alter the course after more is known. While these elements of uncertainty, guesswork, and conflicting opinions, and midcourse adjustments are often seen as a weak decision, this closely resembles the scientific process.

One aspect of economic uncertainty is the relative cost of energy as the transition from fossil fuel takes place. Currently, there is wide interest in natural gas exploration and development with new techniques. This might beneficially impact the

Table 2 Questions that arise concerning the identified four factors of uncertainty with this issue. Again, many questions belong in more than one category

Uncertainty component	*Contributions*
Earth system	How does reducing fossil fuel aerosols affect climate?
	How will polar ice and water levels change?
	How will fresh water and regional climate be affected?
	How much stored methane will be released from ocean clathrates and permafrost?
	How quickly would the Earth naturally restore processes?
	How effective would geoengineering strategies be?
Society collaboration	Will distributed (individuals and states) solutions be identified or will international collaboration be necessary?
	Will sustainable incentives be found to effectively integrate change into the economic system?
	How will blame be assigned and handled?
	Would large centralized solar facilities be targets for terrorists?
Economic health	Will other alternatives be identified (e.g., inexpensive disruptive energy sources)?
	Will renewable energies be relatively less expensive than current energy prices?
	What role will energy play in curbing demand?
	How fast will other countries develop toward the energy intensity of the current developed world?
	Will the future quality of life depend on the current levels of energy intensity in the developed world?
	Will substitutes be found for liquid fuel for transportation?
	How much capital investment and relief will be needed to deal with the environmental disasters and failing states caused by any climate variability?
	Will the prime location of centralized solar power, the deserts, be politically stable?
	Will these uncertainties be reduced enough to encourage the long-term financial commitments necessary for the capital-intensive solar projects?
	What will be the maintenance costs of the projects?
	What relative merits will there be for centralized versus decentralized systems?
	Will smart metering lead to much improved economical use of energy?
	How translatable will the systems be to various parts of the globe?
	Will space costs be reduced to consider space deployment?
Research and development	Will the research subsidies be enough to find a solution to overcome the technological lock-in problem?
	Will the lifecycle costs of the technologies be reduced enough?
	How long will the research and manufacturing learning curves continue?
	Where will the weak link be in the system of energy collection, conversion, storage, and transmission?
	Will the research be dispersed and later focused effectively?
	Will the full environmental impacts be anticipated or will there be surprises?
	What level of renewables will be supported with a limited smart grid?
	Will storage systems, such as hydrostorage and batteries be developed in time?
	If fossil fuel base backup is needed, how much gain in emissions and costs is realized?

transition – through maintaining a relatively smaller carbon emission than coal along with a reasonable price – or be detrimental to the transition by diminishing the incentive to change and invest. As impacts become clearer, the relative bearing of the externality burden from wastes, such as carbon dioxide, will be revisited. The corresponding incentives and taxes will affect the relative cost of the renewable energy. The cost of energy will also have an impact on the relative cost of trade, with higher costs tending to move production to more local sites. The continued global development will affect the energy demand. A quick growth would lead to increased energy growth, although with perhaps more energy-efficient methods. A world with the same energy per capita use as the United States would require the world energy output to increase by a factor of about four.

Research uncertainties are very large in this case; there is little actual deployment and the learning curve is still showing large reductions. The current research covers a very broad range of potential technologies (U.S. Department of Energy 2011a), which probably will be pruned as conclusions regarding development and deployment are reached. Technological surprises might also occur, similar to the discovery of power by nuclear fission in the 1940s. Many researchers are exploring a host of ways to mimic the sun by controlling fusion in terrestrial power plants, but the goal has been elusive; new problems arise as soon as others are resolved. For example, it is known that stable heavy negatively charged particles could catalyze fusion in water very simply, as demonstrated by the (not so stable) catalysis of muons. Progress in the infrastructure is also needed, but large storage batteries are difficult to construct. Sometimes the technology seems close but elusive; for example, the discovery of higher temperature superconductors in the 1980s seemed to offer the possibility of more efficient transmission lines, but both understanding the science and developing the technology have been difficult. Besides the research on actual conversion, change will occur in both energy and material efficiency as lifecycle costs and environmental impacts are considered.

Large uncertainty generates both risks and rewards. For large deployment projects, investors are concerned about the uncertainty of the price, lifetime, and potential displacing alternatives. This is also seen in the nuclear energy sector, where large capital investments are important. Rewards go to the investors who see the opportunity in innovative companies that combine technology, pricing, and opportunities at the right time. Various countries are viewing various renewable energy and infrastructure opportunities with different incentives for attracting investors (Pew Charitable Trusts 2010).

3.06.5 Climate Effects Scope

Climate variability might have a large impact on many systems. The direct effects are those from changes in the weather, which can cause effects that ripple throughout a very complex system with social and technological implications (Figure 5). The boundaries of the effects on this system are difficult to define, especially since the use of solar power might create a feedback cycle by impacting the consequence and probability of climate variability. Some summary descriptions of examples in these areas are listed in Table 3.

The direct effects are changes in the weather such as temperature, storm intensity, average cloudiness, sea level changes, more drought in some regions, and more floods in other regions. These changes would influence where people live and where agriculture might be sustained.

Indirect effects are based on the difference of direct effects on potential substitutes or competing needs. For example, there might be a greater demand for nonenergy-related water supply and land demands might change for food or biofuel crops. In addition, responses might include an indirect effect of pricing consequence through taxes such as a carbon tax.

If the climate variability is large, infrastructure for mitigating the direct effects, such as improved coastal water management, might compete with the need for improved energy transmission and storage. For renewables like solar power, if sufficient storage capability is not established, then backup base-load stations will also have to be a part of the system. These base-load systems might be more directly affected by climate.

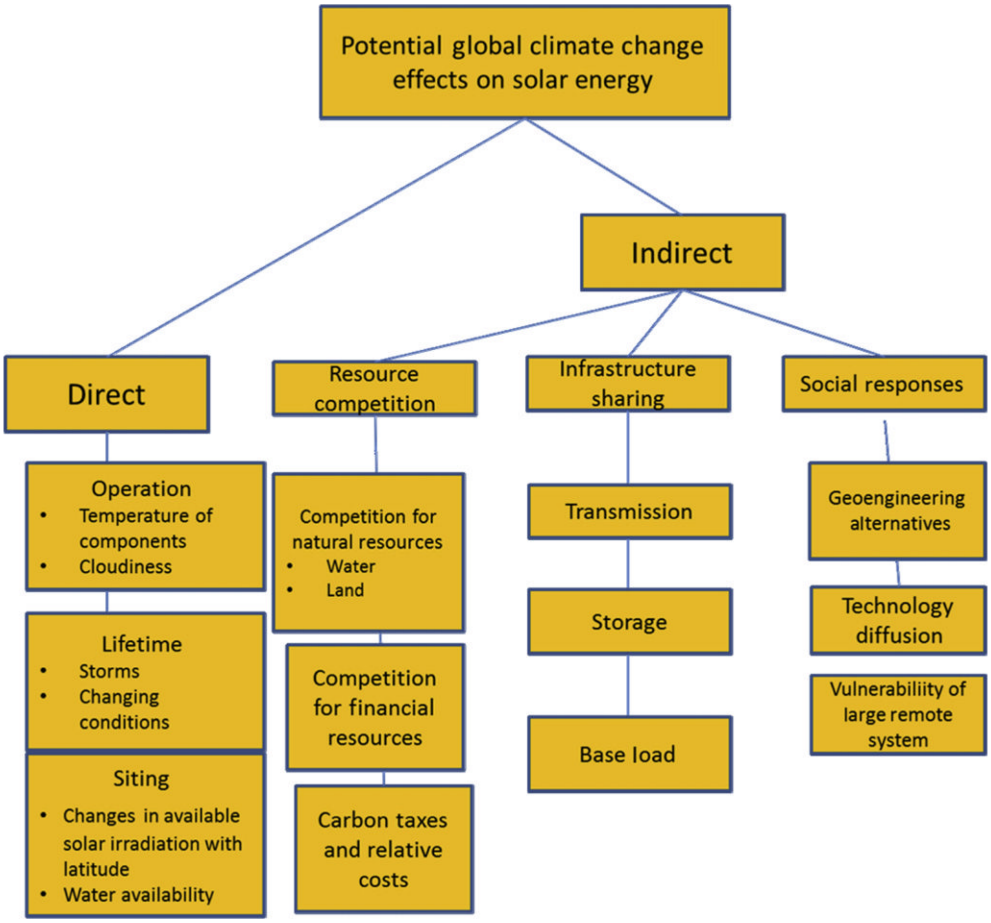
Finally, there are the large effects caused by the ways climate influences societal decision making. Will individuals have the right incentives (e.g., a fair price for energy, including the full impact of the lifecycle of fuel extraction and wastes)? Will collective actions be found? Will perceptions of unfairness in the assignment of fault contributing to climate variability result in international sanctions against countries not cooperating? Will geoengineering be explored?

The impact of climate on solar energy depends both on the level of change in the climate and on the fraction of energy eventually supplied by solar systems. If the relative amount of solar energy remains small, there is little impact. However, dependence on a large fraction of energy from solar plants would increase the sensitivity to many factors such as water, land, and finance.

The lifecycle costs of low-intensity renewable technologies and their environmental impacts on land (McDonald et al. 2009) have yet to be determined.

3.06.6 Analysis

Some general requirements for solar power are access to the sun and, since the raw energy source is free, the capital and land necessary to capture, convert, store, and transmit the energy. The amount of sun that falls on a particular area is affected by the latitude, cloud cover, season, and interfering structures. Near-term climate variability is expected to cause average storm tracks to move northward, leaving higher average sunlight levels to the south (United States Global Change Research Program 2009). Unfortunately, the two requirements of availability and infrastructure costs seem to be opposed. For example, the best place to capture unimpeded solar energy would be in space, but the transmission and material transport costs would be large. The capacity for land to generate solar power is often indicated by arid deserts such as the US Southwest and the African Sahara Desert. Unfortunately, these are also the indications of low population density, and would also require large material transfer and transmission in difficult environments. Important potential impacts are listed in Table 4.



Potential global climate change effects on solar energy

Vulnerabiliity of large remote system

Figure 5 A conceptual categorization of potential global climate change effects on solar energy development. These include direct effects of weather changes on operation, lifetime, and citing. Indirect effects include resource competition, infrastructure development, and potential social responses.

The best case would be something like geospatial orbit where the installation could be in full sunlight 24 h a day without clouds or interfering structures. A problem arises however, when the energy has to be sent down to Earth. Microwaves or space elevators have been proposed to accomplish this, although the technology to accomplish these seems to be in the far future, requiring the cost of space transport to be reduced.

3.06.6.1 Capacity

The Rocky Mountain Initiative has developed a strategy called ‘reinventing fire’ that looks at additional energy efficiency in transportation, buildings, and manufacturing. They all looked at three different energy scenarios of demand and supply. In their business as usual scenario, things get quite a bit worse with price increases being mitigated by increasing energy efficiency only. In their mixed portfolio scenario, there is less pressure but still large uncertainty in providing the energy at a reasonable value. In the advanced energy scenario, alternative renewable sources (wind and solar but not traditional hydropower) supply 30% of energy by 2025. The solar part of this is expected to be 10% of the energy supply with an energy growth factor of 1.5 between 2010 and 2030. This would mean that 2 TWh of power would need to be generated per year. At a 20% collection efficiency, this would mean using an area of 4000 square miles.

Some major factors hindering the current use of solar power are its relative cost, the lack of an infrastructure to support renewable energy, and uncertainty in committing upfront financing while the energy situation is so uncertain (Laitner 2004). One strategy for development is to take advantage of learning curve cost reductions through subsidies and funded research. The dispersed nature of power from sunlight leads to the development of large amounts of land and the development of large complex transmission lines and storage and/or backup systems. While very large-scale growth of solar to the point where it would dominate the energy portfolio is a long way off (e.g., over the 50 years the President’s Council of Advisors on Science and Technology (PCAST) estimated to change the energy system), the more feasible goal of supplying 30% of energy by 2025 does not seem to be hindered by many factors of potential from climate change. One factor that may play a part is the availability of financing, especially if large climate variability happens before the learning curve can achieve cost comparability between solar and other resources. The funding to respond to local efforts, and of developing countries to respond to potential humanitarian efforts, might diminish the financing needed. Other organizations at smaller levels, such as the business group, realize the potential interconnected issues and threats and so are developing their own strategies for possible collaboration.

Table 3 Potential effects of climate on solar energy systems. A categorization of effects as direct or indirect is given in **Figure 4**. While the direct effects of temperature, cloudiness, storm intensity, and water availability will impact some areas, a major effect is caused by the more complex indirect effects such as competition for financing for both the energy collection sites and the corresponding infrastructure. Social responses concerning the ability to develop and maintain the systems are also a factor

Type of effect	*Climate effect*	*Effect on solar energy development*
Direct	Temperature increase	● Effect on water heating beneficial (Bengtsson 2007). ● Solar cell efficiency changes with temperature and can rise above the ambient temperature. ● The change would be different in different places, leaving some places ill-suited for solar energy while increasing the utility at others. ● Water from rain and runoff might change, leading to competition for water. Water is necessary for the thermal engines of concentrating solar and in smaller amounts for washing PVs.
	Cloudiness	● Clouds would obscure sunshine, reducing return.
	Storms	● Large structures are needed to collect the dispersed sunlight energy. The structures need to be capable to withstand the most intense storms, leading to increased construction and/or maintenance costs. ● Larger fluctuations of temperature or conditions may lead to quicker material degradation, thereby leading to shorter lifetimes.
Indirect competition	Land	● Large amounts of land are needed for the collection of dispersed solar energy. The land might be needed for other purposes such as agriculture or conservation. Some desert land when disturbed might release particulates and organisms that cause diseases.
	Financial resources	● Climate variability might increase demand for large infrastructure projects such as levees and flood control. This might put pressure on financial resources to construct large, capital-intensive renewable projects.
	Externality costs	● With more information coming in on impacts from various wastes, including carbon dioxide, the inclusion of the externality costs of various energy sources might be included (e.g., carbon tax).
Infrastructure sharing	Transmission	● Large-scale systems might occur in deserts far from large populations, requiring long transmission lines. These lines might be more susceptible to severe weather.
	Storage	● Storage is needed to balance the supply of solar energy to the demand. Currently, many small hydropower dams are used. Climate might affect the suitability of these storage systems.
	Base load	● To assure availability of power when renewables might not be producing, backup power systems are needed. Their intermittent starting and stopping might not be energy or environmentally efficient.
Social responses	Geoengineering alternatives	● If it is believed that geoengineering solutions might be less costly and more effective at mitigating climate effects, the incentive to develop and deploy renewables might be diminished.
	Technology diffusion	● The regional types of research and manufacturing might change in response to climate or availability of investments.
	Vulnerability of large remote systems	● Large remote solar power facilities might be more susceptible to disruption through local development or social protest.

Solar cell production costs continue to decrease with a pattern similar to Moore's Law for computer chips (Naam 2011; Greening et al. 2000; Arvizu 2006). The pertinent question is how to support research leading to an initially broad search but then focus on specific beneficial technologies without technological lock-in. The appropriate technology paths have been developed and revised (Edmonds et al. 2000). Various views of this question have been addressed by government agencies (Hanson and Laitner 2006; Hanson et al. 2004), the president's council advisors on science and technology (President's Council of Advisors on Science and Technology (PCAST) 2010), business groups (American Energy Innovation Council 2010), and local decision makers (Green Rhino Energy 2010).

With these considerations, there might not be a need to put a whole new energy capture, conversion, transmission, and storage system together soon. In fact, the PCAST concluded in November 2010 that to fully transform the US energy infrastructure would take about 50 years. Currently, only about 15–20% renewable sources can be integrated into the system without a large number of storage systems or backup energy generation systems. A backup system might be needed when the renewable sources are not active (at night for solar) or when no wind is blowing for turbines. The backup systems might be natural gas turbines, although some locations might use excess coal power ramping, which might be as efficient as running continuously. For storage systems, the main applications are using small hydropower systems to pump water up with excess electricity and let it flow down when it is needed. Compressed air also has a large current potential for storage, although much research is being done to identify scalable battery systems. The current storage amount of such systems varies; about 10% of US electricity, 15% of European electricity, and 20% of Japanese electricity is typically temporarily diverted. Research continues on finding electrical batteries that meet various storage requirements (Dunn et al. 2011).

3.06.6.2 Other Goals

Obstacles to energy development might be helped by considering factors other than just from climate change. Three dimensions identified are economic, national security, and other environmental impacts. In the economy, oil imports

Table 4 Summary of important potential climate effects on solar energy production. Other vulnerabilities are also identified; while not directly tied to climate, the impacts might result in unexpected disruptions in the system

Timescale	*Vulnerabilities to climate effects*
Short term	● Lack of storage on grid. The current system would be able to support about 20% intermittent renewables before the system would fail to keep balance. Hydropower energy storage is currently being used, but other systems for battery storage are being pursued. ● Potential for technological lock-in of a suboptimal system if the R&D is too diffuse or too focused. The market dominance of a suboptimal technology might later limit expansion because of cost or capacity characteristics. ● Competition for finance with other energy projects and investments due to climate variability. With uncertainty so large, perhaps distributed systems might grow first, demonstrating capabilities. The ability to decrease the overall cost, including the installation and customization, is being addressed in the $1/W program.
Medium term	● Technologies might not diffuse as fast if material and production resources are not distributed. This would be especially true with rising transportation fuel costs. ● Large-scale systems need time to be developed and tested. One estimate is about a 50-year time scale to redevelop the US energy infrastructure. ● Large-scale systems might be developed in the desert, which would require weather and social stability to realize long lifetimes and reduce lifecycle costs. ● A technological surprise might disrupt the need for these systems collecting the diffuse solar energy. Currently there is a wide search in many countries for alternatives such as a more compact fusion energy source.
Long term	● Global development might continue to require more energy per person. This may lead to alternative places to collect and transmit solar energy, such as in space. This would require a drastic reduction in the cost to put material into space. It would probably require international collaboration on a scale larger than the ITER (International Thermonuclear Experimental Reactor) fusion reactor. A full deployment would probably have to be broken into purposeful steps, supply niche needs, and demonstrating capabilities (Landis 1990).

distort both the trade payments and political dependency on exporting countries. Often, these countries might be politically adverse with access to a trade chokepoint such as the Straits of Hormuz. Environmentally, there are other impacts from pollutant gases (NO_x from natural gas use and SO_x from coal use), particulates released from fossil fuel burning, uncertainties about water-energy needs, and nuclear waste.

By looking at the energy problem from multiple goal perspectives, alternative strategies might be discovered (Richter 2011); for example, in the case of the investment in PV solar in California's Million Solar Roofs project, 15% of the cost could reduce as much greenhouse gas as converting an old coal electricity generating plant to use natural gas. In addition, it might foster collaboration between different groups. For example, the American Energy Innovation Council could collaborate with CEOs to form a nongovernmental strategy for energy development.

There is much debate on whether potential climate variability should be considered a national security issue (Matthew 2011). One factor of not acting is the potential opportunity cost of not leading the R&D of new technologies. Other countries, such as China, have already invested quite a bit in developing manufacturing (Lacey 2011). China has quite a bit of investment funding available, while the United States and Europe are considering the impacts of long-term debts. However, not just impacts on each country but potential costs of responding to a series of humanitarian crises might occur if environmental change happens.

3.06.6.3 Research

Many renewable energy technologies depend on discrete energy exchange at the nanoscale levels over very short timescales (Crabtree and Sarrao 2011). Control and understanding of these phenomena require special tools for studying semiconductors, metals, and molecules for capture, conversion, storage, and transmission. Many of these processes are not well understood (e.g., relatively high-temperature superconductors that were discovered about 25 years ago). Often complex materials with small-scale structures or elements control are required to construct these complex materials. New tools such as time-resolved X-ray scattering coupled with detailed computer models are helping determine the path to potential solutions.

An additional problem with research is finding ways to benefit from it with patents while still allowing advances to proceed. There are concerns about recent subsidies and environmental controls at Chinese solar cell manufacturing locations that have recently dominated the production market (Hickman 2011). The financing is interesting because many of the developed countries are experiencing debt crises with concerns over large long-term investment, whereas the Chinese have the largest financial resources to invest.

3.06.7 Methods

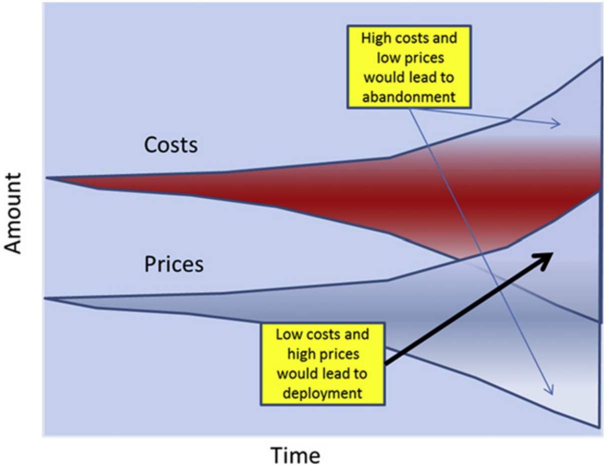
Real options analyses facilitate assessment of flexible technology options in quickly changing situations with large uncertainties for actions that might be irreversible. These situations occur in technology-driven decisions where technology, regulations, markets, and scientific understanding quickly evolve (Amram and Kulatilaka 1999). Examples of areas where these conditions often occur are national security, environmental risk management, and applications of advanced technology. Whereas traditional assessments rely on specific alternative actions with few flexible decision points, ROA, an extension of the financial community's options methods, also considers the impact of flexible decisions, such as delaying, switching, expansion, and abandonment, in uncertain conditions, such as fluctuating costs.

The well-known Manhattan Project conducted during World War II is an interesting research case that can be viewed through ROA. The goal was to try to find a way to construct a nuclear explosive device (before the other side did). The most difficult part of the process was to collect enough special isotopic material to form a critical mass. Research showed that there were many potential ways to collect this material (including differential thermal diffusion, magnetic mass separation, gaseous diffusion, and reactor production), but it was unclear which were quicker and more efficient. As a result, many potential options were simultaneously tried. Some methods, after great investments, did not deliver as originally thought. Others were revised as research findings led to reconsideration of the priorities. The great uncertainty and motivation for the research was the threat that the other side (considered between Germany and the United States) would discover the secrets and use the new weapon first. As the war wore on, indications of German research in this area were observed and sabotaged. Near the end, when the decision of deployment was to be made, multiple limited successful special material collection techniques were implemented. Just before the final test of the system, the main motivator was reduced to zero (German surrender without nuclear weapons use).

For example, ROA might be applied to assess portfolios of geoengineering (Lempert and Prosnitz 2011) or renewable energy development options (Siddiqui et al. 2005) to address climate variability. The geoengineering technology options include carbon capture and sequestration, cloud seeding, space-based reflectance, and ocean fertilization. Uncertainties in environmental impacts are aggregated into the uncertain impact cost of carbon emissions (Royal Society 2009). The experience curve model was used for predicting technology development progress. Technology-specific assessments to support this model are being discussed. This model extends previous ROA applications to energy research and environmental technology investment. This technique not only evaluates the research portfolio under uncertainty but also results in intuitive explanations for the various scenario paths. A further benefit can be achieved if the analysis is periodically updated with the actual R&D results and cost fluctuations.

Dynamic analysis can be accomplished through ROA or uncertainty analysis. While 'road maps' are often generated for a technological path, the uncertainty of the technology, collaboration, and impacts would seem to favor a more flexible approach. The approaches might include ROA or parametric uncertainty analysis. These approaches would allow for flexibility but allow qualitative mental models to be constructed and communicated to the public and financial community. The models are capable of accepting new data on the state of the environment, collaboration, and technological research outcomes.

Some requirements for this analysis are constructing a framework of research dependence including serial (i.e., where two branches of research would be used together) and parallel (i.e., where either of two branches of research would be applied). The research would be characterized by parameters such as research costs, the state of uncertainty, potential reduction of uncertainty by research, and potential value of the research outcomes. A large amount of uncertainty resides in the relative costs of fossil fuels, such as oil and natural gas, along with the cost of emission of CO_2 and other greenhouse gases (Figure 6). With ROA, these might be modeled as a lognormal diffusion process. Besides the data on the research and financial environment, decisions rules would have to be made explicit (e.g., research continuation, abandonment, enhancement, and transition to development and deployment). The tool might be used to analyze various research and development incentive policy options, such as collaboration between governments, nongovernment organizations (NGOs), and private industries.



High costs and low prices would lead to abandonment
Costs
Amount
Prices
Low costs and high prices would lead to deployment
Time

Figure 6 Schematic graph of the uncertainty of the costs and prices for the solar energy deployments. Costs are impacted by the results of research, production learning curves, and availability of materials, land, and other resources. The price for the energy is determined by the relative success of competing technologies and demand, which is influenced by energy efficiency levels and global development. Price is also affected by the incorporation of actual costs such as waste (e.g., potential carbon dioxide tax). A real options analysis would reflect these uncertainties along with the learning curves to assess the value for continuing, accelerating, or abandoning certain research and development paths.

There are some trends in aggregate measures of energy use such as the logistic substitution patterns in the fractional use of energy sources over time and the trend in the reduction of the C:H ratio in primary fuels. These trends might provide a bound on the potential scenarios at later times where larger uncertainty arises.

A ROA project would include the following:

- A framework with research estimates. The framework would include sequential and parallel dependencies of research paths and weighted by future contributions based on energy scenarios.
- A ROA for this framework, focusing the uncertainty in the fossil fuel costs with the CO_2 costs folded in.
- Information about data needs for a detailed model (e.g., technology options and uncertainties include potential costs, environmental impacts, and likelihood).
- Dynamic criteria and rules for the dynamic decision options.

It is hoped that the project would demonstrate the benefits of the dynamic decision support tool for research. It should increase confidence in the overall strategic approach to the research investments by allowing for the uncertainties and relationships of the processes to be accounted for and communicated.

Consider that case with two potential competing technologies, each with a different learning curve. The price of carbon might increase or decrease from an initial price, diverging in time. The cumulative R&D costs increases with time, for example through a fixed annual budget. An option might be to fund a small amount of research on one technology resulting in a relatively high unit cost, or much research could be done on the other technology resulting in a relatively lower final cost. If the final state involves small climate variability consequences, then the first technology might be effective. If the final state involves large climate variability, the second technology might be preferred.

Learning curves (or experience curves) have been studied for about 75 years, starting with the observation that as more planes were built, learning-by-doing occurred, leading to lower production costs. The concept is that as more of an innovation is produced, the cost gets lower. The empirical pattern is that a doubling of the aggregate production results in a nearly constant fractional decrease in the costs. However, this can lead to the potential market failure of technological lock-in, since only early technologies, not necessarily the best, would tend toward lower costs and market dominance. Understanding the learning curve and potential costs savings and advantages of technologies leads to estimates of the investment (often governmental subsidy) necessary to encourage effectiveness in the long run (Alberth 2008). Learning curves were used in an integrated energy model of Gritsevskyi and Nakicenovic (2000). They concluded that R&D efforts need not be so focused on one technology but instead on a cluster of related technologies, although they should not be spread out too much. As the research and situations are better understood, the portfolio of technologies can be pruned. Recently, a learning-curve tool, EXTOOL (Neij et al. 2003), has been developed in Europe to consider different aspects of wind power generation.

3.06.8 Conclusion

The future of solar power depends on the results of research to find relatively inexpensive ways to convert, transmit, and store solar power. This is not easy. Climate directly impacts the availability of land, and solar power is rather diffuse. Collecting and using this distributed power would require a smart grid to coordinate the collection and a backup base-load system if storage capabilities are not adequately found and deployed. Regional effects such as increased cloudiness and violent storms would impact the collection and maintenance of solar systems.

PV systems do not require much water for operation, but they currently depend on special elements that might become expensive or geopolitically controlled. Research is being conducted to find alternate methods that do not depend on these materials.

While electricity would be a major product of the solar concentrator and solar PV systems, a major use of current fossil fuel in transportation is one not currently easily replaced with electricity. This leaves several options that are being pursued: developing an efficient storage system, charging on the go, or converting solar energy into high-energy-density fuel.

Climate variability impacts solar power through impacts on substitutes as the real price of their operation is better established. While much information needs to be obtained and understanding better developed, one way to look at the problem is as insurance. A case that would cause some difficulty is one where research and development were not ready and effects were causing increased demand for capital to maintain systems such as water management.

Acknowledgments

The submitted manuscript has been created by UChicago Argonne, LLC, Operator of Argonne National Laboratory ("Argonne"). Argonne, a U.S. Department of Energy Office of Science laboratory, is operated under Contract No. DE-AC02-06CH11357. Millennium Development Goals (MDG) is a roadmap of goals based on the United Nations Millennium Declaration:
End poverty
Universal education
Gender equity
Child health
Maternal health
Combat HIV
Sustainability
Global partnership

3.07.1 Introduction

Climate will increasingly affect all aspects of modern societies, global and national economies, energy, underlying infrastructures, as well as all political institutions. The collective effects will cause extensive societal vulnerabilities, whether developed or developing. As such, the increased risks require realistic adaptation responses. In planning responses to the risks, civil and political authorities will have to primarily consider impacts on infrastructures of societies.

The year 2011 was a significant year in the statistics of natural disasters for the past decades, 1981–2011. The total cost of the natural disasters in 2011 was the highest during the aforementioned period and for the first time in the history of the last 30 years the trade deficit of the export-oriented Japan was negative in 2011.

The energy infrastructure is a part of the global infrastructure. Infrastructure consists of durable resources that are classified as 'collective goods' generating external effects. The development of income and standard of living in a society is highly dependent upon its energy resources. During the last decade the productivity growth has been stagnating in the Western industrial countries, thereby reducing the base for private and public consumption. A common characteristic of the industrialized countries is that a diminishing percentage of GNP has been allocated to public investments, leading to reduced growth of the infrastructure stock. This has been happening independently of any climate effects. In this context, we should make a distinction between material and nonmaterial infrastructure. Nonmaterial infrastructure includes the existing technological and organizational knowledge and social networks. On the other hand, the material infrastructure is defined as all physical networks for transportation and communications; that is energy and water supplies, roads, railways, airports, harbors, and construction for post and telecommunications.

Many efforts have been made to define infrastructure. The most restricted description is that infrastructure can be identified from the following attributes (Sarafoglou et al. 2006):

1. Infrastructure is durable capital with a fixed location, and its services have spatial extension, although the benefits decline as distance increases.
2. Infrastructure services satisfy at least one of the following features: (1) polyvalence, (2) temporal generality, and (3) systematic or network functions.

However, the most common definition is that infrastructure is a resource that can be used collectively by many firms and households. Thus infrastructure may be seen as a potential between people and markets.

The importance of different elements of the infrastructure varies among countries and regions depending on, for example, geographical conditions, levels of economic development, and

http://dx.doi.org/10.1016/B978-0-12-384703-4.00316-6

sectorial mix of industries. It is important to point out that although the link between economic growth and infrastructure investment is generally strongly accepted by different authors, there are divergent opinions about the quantitative evaluation of the link. The linkages between the energy infrastructure, the transport infrastructure, building infrastructure, and the other forms of infrastructure are also important. For example, a price increase in oil will increase the cost of the transportation infrastructure as well as the cost of capital (e.g., buildings). The interrelationships among the various infrastructures are critical for national economies, and the use of the systems approach is necessary to quantify and assess these interrelationships.

The UN Secretary-General Ban Ki-moon (UN 2011) declared that "Energy is the imperative of the twenty first century." The purpose of this chapter is to analyze the role of energy infrastructure for various economies, the vulnerability associated with energy production and consumption processes, and finally the use of the new paradigm of sustainability in a world increasingly affected by climate.

A sustainable energy infrastructure might be considered one of the most critical policy variables to deal with environment and climate in the future.

Section 3.07.2 presents some facts about energy infrastructure and-methodological assessments. Section 3.07.3 discusses the various aspects of climate vulnerability and energy. Section 3.07.4 presents definitions of hazards and disasters. Disaster databases are reported in Section 3.07.5, whereas precautionary disaster policy is given in Section 3.07.6. In Section 3.07.7, a survey of the concepts of sustainability, sustainable development, and sustainability science is written. In Section 3.07.7, the IPCC and the Stern review are critically reported. Finally, energy futures are discussed in the last section.

3.07.2 Some Facts about Energy Infrastructure and Methodological Assessments

In mythology, energy was connected with the gods. The term energy (*energeia*) was used by Aristotle in his book *Nicomachean Ethics* (fourth century BC).

Kaku (2011) wrote about solar energy in Greek mythology:

> The stars were the energy source of the gods. When Apollo rode across the sky in a chariot drawn by fire-breathing horses, he illuminated the heavens and the earth with the infinite power of the sun.

Energy is one of the most fundamental concepts in physics, but generally, energy means potential for work or change, a rather imprecise definition. On the contrary, energy infrastructure has a definition. The economist Nicholas Georgescu-Roegan advocated in his ground-breaking book (1971) that the economic system was actually a general thermodynamic systems.

The energy infrastructure includes the electricity grid of transmission lines, the physical network of pipes for oil and gas, the rail network, marine transportation, and truck lines. The electricity infrastructure consists of power plants fueled by coal, oil, or gas. We are discussing here the electric grid and not portable (battery), or alternative energy sources (e.g., wind, photovoltaic, and ocean wave energy production). Human climate forcings, such as carbon dioxide and aerosols from fossil fuels, land use management, and so on (NRC 2005), may generate climate instability and lead to extreme weather events. These instabilities and extreme events can cause critical water and food shortages for many people on earth.

There are some path-breaking works in the history of energy-related issues. W.S. Jevons' book *The Coal Question* (1865) was an early economic analysis of the depletion of coal resources. The mathematical economist Hotelling (1931) developed an intertemporal price mechanism for nonrenewable resources. The bell-shaped curve of world oil production was developed by the geologist Hubbert (1956). This is the so-called Hubbert's peak. His prediction of the 1970 peak of US oil production was verified.

Two main complementary approaches have been used to analyze the role of energy infrastructure:

1. A parametric approach using the Cobb–Douglas production function.
2. A nonparametric approach using Data Envelopment Analysis (DEA).

A common characteristic in infrastructure literature is the production function formulation relating value-added output Q to the quantities of input L, private input C_p, and public infrastructure C_i.

If the parameters of this formulation of production function are estimated, the resulting method is termed the parametric approach. The following production function is a typical parametric application in which the parameters are estimated by the use of econometric techniques.

$$Qk = F(L, C_p, C_i)$$

Various specifications of the production function have been used. The Cobb–Douglas function is still the most frequent specification. More complicated functions have also been applied, such as the trans log function and the Mills and Carlino formulation (1989).

However, a number of infrastructure studies may be found in which public infrastructure capital C_i has not been incorporated into their production or cost functions. An obvious implication of this misspecification in which the C_i is an omitted variable is that all the empirical results may suffer from an omitted variable bias.

In the nonparametric approach (DEA), the parameters of the production function are not estimated, but relative efficiency indices are calculated reflecting input–output differentiation among various units. The name DEA derives from the procedures applied to observational data used to establish efficiency frontiers via an envelope function of all production process. A mathematical programming model applied to input–output data gives estimates of extremal input–output relations similar to the production function. Forsund and Sarafoglou (2002) offer a historical review of DEA in economics and operations research. An excellent survey of energy and environmental modeling using DEA and other nonparametric methods can be found in Zhou et al. (2008). Emissions are classified as undesirable outputs in the DEA approach.

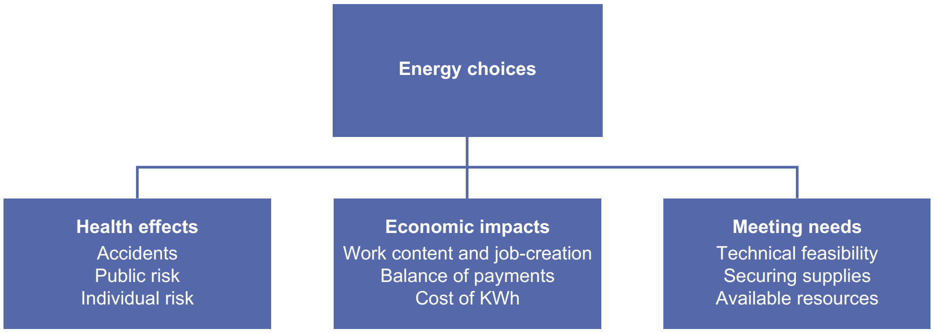

Figure 1 Energy choices. Source: Siskos, J., and P. Hubert, 1983: Multi-criteria analysis of the impacts of the energy alternatives. *Eur. J. Oper. Res.*, **13**, 278–299.

The compatibility of the parametric and nonparametric approaches might be rather unsatisfactory, but future development seems promising.

Another approach to estimate the economic effects of infrastructure investments is cost benefit analysis (CBA). In CBA, the economic effects of the infrastructural investment are measured as increases of the consumer surplus of the estimated demand function.

Energy choices are very important because they generate health effects, economic impacts, and the efficacy considerations for workers, users, and the public. Siskos and Hubert (1983) wrote an interesting application of multicriteria analysis (MCA) of the impacts of energy alternatives in France.

The energy infrastructure has a direct impact on the labor market: job creation, work content, and job elimination are related to the energy choices.

The balance of payment can be changed by the value of energy imports. The cost of KWh is an extremely important factor for energy decision making of individuals, government agencies, and firms (Figure 1).

How can governments meet the energy needs of their citizens and corporations in the era of globalization?

What is the optimal distribution of domestic energy production and energy import given the political instability of the world? The risks related to the production, distribution, and use of energy are critical for economic systems as well

3.07.3 Climate, Vulnerability, and Energy

It was mentioned earlier that climate will increasingly affect all aspects of societies, economies, energy, underlying infrastructures, and political institutions, as well as the world's ecosystems. The collective effects will create extensive vulnerability in societies, whether developed or developing.

Rockstrom et al. (2010) tried to link the three disconnected processes (climate, ecosystem, and Millennium Development Goals (MDGs)) in Figure 2. Climate, including possible changes in regional and local climatology, is a major threat to the ecosystem and to human society. Environmental degradation and biodiversity loss are also big challenges for the climate and the human population. Anthropogenic emissions can influence the ecosystem and the climate.

Svante Arrhenius, a scientist from Uppsala (Sweden) and a Nobel laureate, developed the theory in '*Varldarnas utveckling*' (1906) that changes in carbon dioxide quantity in the atmosphere could change the earth's temperature through the hothouse or greenhouse effect.

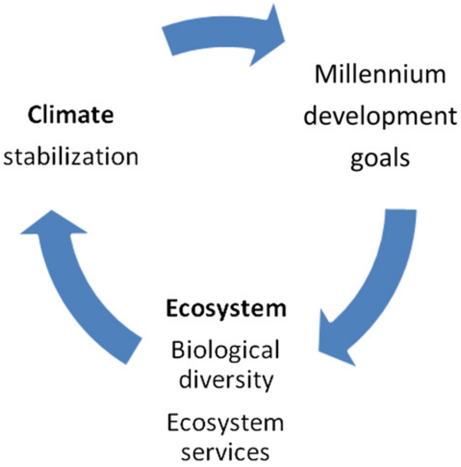

Figure 2 Disconnected critical processes. Source: Rockstrom, J., et al., 2010: Making progress within and beyond borders. *Global Sustainability*, H. J. Schellnhuber et al., Eds., Cambridge Univ. Press.

> By the influence of the increasing percentage of the carbonic acid (CO_2) in the atmosphere, we may hope to enjoy ages with more equable and better climates, especially as regards the colder regions of the earth, ages when the earth will bring much more abundant crops than the present, for the benefit of rapidly propagating mankind.

and Arrhenius' greenhouse law can be formulated:

> if the quantity of carbonic acid increases in geometric progression, the augmentation of the temperature will increase nearby in arithmetic progression.

Arrhenius' temperature increase forecast for the doubling of CO_2 in the atmosphere was very accurate in the precomputer era. It is interesting to note that, the hothouse or greenhouse effect was forgotten by scientists until the 1960s.

Vulnerability might be considered as a function of vulnerability of assets and resilience of non-assets. The IPPC's definition is that vulnerability is the propensity of groups, systems, or persons to suffer harm, or anticipate and cope with, resist, and recover from stressors. The World Bank and UN definition (2010) is rather similar to IPCC's: Vulnerability is a characteristic that influences damages in physical assets (building architecture, codes, and strength), social capital (family networks, trust, social structure), and political access (government help and participation in policies).

Another definition of vulnerability was given by the Friibergh *Workshop on Sustainability Science* (2000) in Sweden, vulnerability can be defined thus:

> Vulnerability analyses seek to evaluate the risk of adverse outcomes in the face of climate variability and longer-term change and the other relevant causal factors that co-exist with climate.

Vulnerability (V) can be seen as the difference between Cumulative Impacts (I) from multiple stressors and Adaptive Capacity (AC):

$$V = I - \mathrm{AC}$$

There are many perspectives on vulnerability. In Pielke's web page (2011) there are two other perspectives:

A. Outcome vulnerability
B. Contextual vulnerability

The first vulnerability is an IPCC-based climatic vulnerability. The second vulnerability is bottom-up and has higher complexity in terms of institutional, economic (water, food, health, and energy), and social structures, climatic factors, and finally ecosystems.

The global energy generation process is quite complex and has a high spatial concentration. Changes in environmental and climate statistics can generate undesirable energy infrastructure shortages (Paskal 2010).

We know that the energy infrastructure has a long lifespan (50–100 years), high building costs, and high maintenance costs. The Hoover Dam in the United States is 75+ years old, the first English nuclear in Calder Hall was in use during the period 1956–2003, and so on. It is difficult to maintain the old energy infrastructure so as to satisfy modern environmental impact assessments. If there are changes in precipitation patterns, then precipitation-dependent hydroelectric power stations could face new difficulties. Deforestation could generate landslides and affect the flow of hydroelectric power plant water.

During the hot 2003 summer (temperature $>40\,^{\circ}\mathrm{C}$) in Europe, many nuclear plants had to be unused, and European countries imported energy at higher prices. Higher energy prices can increase national economies' budget deficits.

Other weather-related events can harm national and regional economies. Hurricane Katrina in 2005 damaged almost 20% of the United States' refining capacity. The city of New Orleans lost almost 25% of its population during the post-tornado period.

Cold weather has stopped the oil flow of the Alaska pipeline many times during the last 10 years. The world consumption of oil today is almost $160\,000\ \mathrm{l\,s^{-1}}$. The spatial distribution of oil production is concentrated in politically unstable regions (e.g., OPEC nations).

The distributional aspects of energy consumption are also important to mention here for energy vulnerability: Nine million Swedes consume more energy than Indonesia's 200 million citizens.

In other words, the uneven spatial distribution of energy supply (e.g., OPEC nations) and energy demand (e.g., developed countries) increases global vulnerability.

3.07.4 Hazards and Disasters

Natural disasters have a long historical record. Plato in his dialogue *Timaeus and Critias* (360 BC) described that Atlantis (the island of Atlas) sank into the ocean in ~9000 BC "in a single day and night of misfortune." This information was confirmed by reading the Egyptian hieroglyphs and was disseminated by the lawmaker Solon.

Although the terms hazard and disaster have an overlapping meaning in everyday life, they are assumed to have different meanings here.

Hazard is a probability of a natural event that might cause harm and should be estimated by experts, whereas disaster is the output of a hazard and might be estimated by a multidisciplinary team of experts.

The risk exposure is a function of the population and assets in a given area.

Countermeasures to reduce vulnerability can be classified according to World Bank:

- Mitigation (to minimize GHG emissions so as to minimize extreme weather events)
- Prevention (to build a plinth-wall for floods)
- Preparedness (to plan building evacuations)
- Relief (to help people after a disaster)

Finally, disaster risk is a multiplication of hazard, exposure, and vulnerability.

Total disaster impact is the sum of direct and indirect effects. Direct disaster impacts can be estimated in terms of human and capital loss. Indirect disaster impact in an economy is more complicated to estimate because it deals with the changed structure of the economy (e.g., production, consumption, employment) after the disaster.

Other socioeconomic factors are extremely important to gauge total disaster impact. The level of development of a nation is critical for the absorption of disasters. For example, Haiti's last earthquake was less on the Richter scale than Chile's last earthquake, but damage absorption was much better in Chile than in Haiti.

The development of the theory of economics on natural disasters since the seminal work of Dacy and Kunhreuther (1969) has been modified and directed to the economics of climate (Nordhaus 2006; Stern 2007).

The insight of this research-evolution is that global warming might be the cause of most natural disasters. The empirical work for the effect of natural disasters on national economies in terms of capital and human losses has been increased in the last 20 years (Alexander 1997; Cavalo and Noy 2009).

Although there is no widely accepted definition of natural disaster, the CRED definition from Belgium is used here:

> Situation or event which overwhelms local capacity, necessitating a request to national or international level for external assistance; an unforeseen and often sudden event that causes great damage, destruction and human suffering.

Preventing disasters means using policies that minimize exposure and vulnerability to human suffering and destruction. Exposure relates to the people and property subject to hazard. It is a function of population density and location indicators.

These three factors determine how some communities can absorb disasters and recover more easily than others.

Natural disasters can be classified into three categories:

1. Hydro-meteorological: floods, droughts, landslides
2. Geophysical: earthquakes, volcanic eruptions
3. Biological: epidemics

The severity and frequency of disasters in the last several decades have generated an increased interest in data and methodologies to better understand disaster complexity. Disaster impact on the development and growth of nations became an important issue for investigation.

The prediction of disasters has been one of the main themes for many research works in social and natural sciences. Ongoing improvement in data quality may lead to increased disaster prediction accuracy.

Disaster issues have been investigated by both natural and social scientists (mainly economists, sociologists, and political scientists) in an interdisciplinary way. A more holistic disaster approach has been conducted by scientists lately, which is very promising.

Finally, a 'before the disaster' policy can be exemplified by the reallocation of the Tokyo metropolitan area. A review of this is given in Section 3.07.6.

Public policy makers need more quantitative data so as to assess disaster risks and generate preparedness and mitigation planning.

3.07.5 Disaster Databases and Methods for Estimation of Disasters

Questions such as "to what extent can existing data and methodologies be reliable for disaster assessment" are important for public policy makers.

The lack of systematization and standardization is the main problem of disaster statistics. Data collected by insurance companies for risk management can be biased. Low-income countries or groups are not included, because they can afford insurance policies and costs.

1. Emergency Events Database (EM-DAT) generated by the Center for Research on the Epidemiology of Disasters (CRED) at the University Catholique de Louvain, Belgium (www.cred.be). This database (**Figures 3 and 4**) has been generated from various agencies (e.g., UN, insurance companies). EM-DAT covers only direct damages (i.e., damage in housing, infrastructure, farming and number of people killed during the-disaster).
2. Sigma, Swiss Reinsurance Company.
3. NatCat, Munich Reinsurance Company.
4. Disaster Database Project, University of Richmond.
5. Hotspots Project Database, Center for Hazards Risk Research, Columbia University.
6. Google Insights Google has developed a database based on web search statistics. The web search database might be very recent (e.g., 2- to 3-days-old data) and is a proxy of an event.

The most frequent methods for estimation of disasters are the UN-ECLAC and the econometric methods (Albala-Bertand 1993; Noy 2009; Okuyama and Sahin 2009).

A simple econometric model used by Cavalo and Noy (2009) is:

$$\mathrm{DIS}_{\mathrm{it}} = a + bX_{\mathrm{it}} + e_{\mathrm{it}}$$

where the variable DIS measures the material and human losses of country i at time t, the variable X_{it} measures the disaster magnitude and vulnerability of the country, and e_{it} is the error term.

The level of economic development of a country in terms of per capita GDP may increase its vulnerability to the impact of natural disasters.

The rationale of this hypothesis is that developed countries have more mitigation policies to minimize the effects of disasters (e.g., political stability, property rights, earthquake engineering, and better urban and rural planning).

Dacy and Kunreuther used a simple neoclassical version of Solow–Swan growth model of capital stock (K) and labor (L):

$$Y = f(K_{\mathrm{p}}, K_{\mathrm{b}}, K_{\mathrm{r}}, L)$$

where the capital stock has been disaggregated in public capital (K_{p}), business capital (K_{b}), and residential capital (K_{r}).

The optimal path of recovery can be examined by imposing marginal productivity conditions. In this type of model, technological replacement is more critical than technological progress. More sophisticated growth models with endogenous technological progress can be used in a natural disaster context.

Spatial econometric models of natural disaster impacts have been used as well. Space, friction, spatiotemporal components, externalities, and many other aspects interact and should be treated adequately in spatial econometrics (Sarafoglou and Paelinck 2008; Saldana-Zorrilla and Sandberg 2009).

Alternative methods for the estimation of disasters are as follows:

1. International Institute for Applied Systems Analysis (IIASA) Models
2. Input–Output Models
3. Social Accounting Matrix Models
4. Computable General Equilibrium Models
5. Geographical Information Systems and Remote Sensing

3.07.6 Precautionary Disaster Policy and the Great East Japan Earthquake

The role of environmental factors and risks in the decision making of 'relocation of capital functions' out of Tokyo is given in this section. The short- and long-term costs of the great

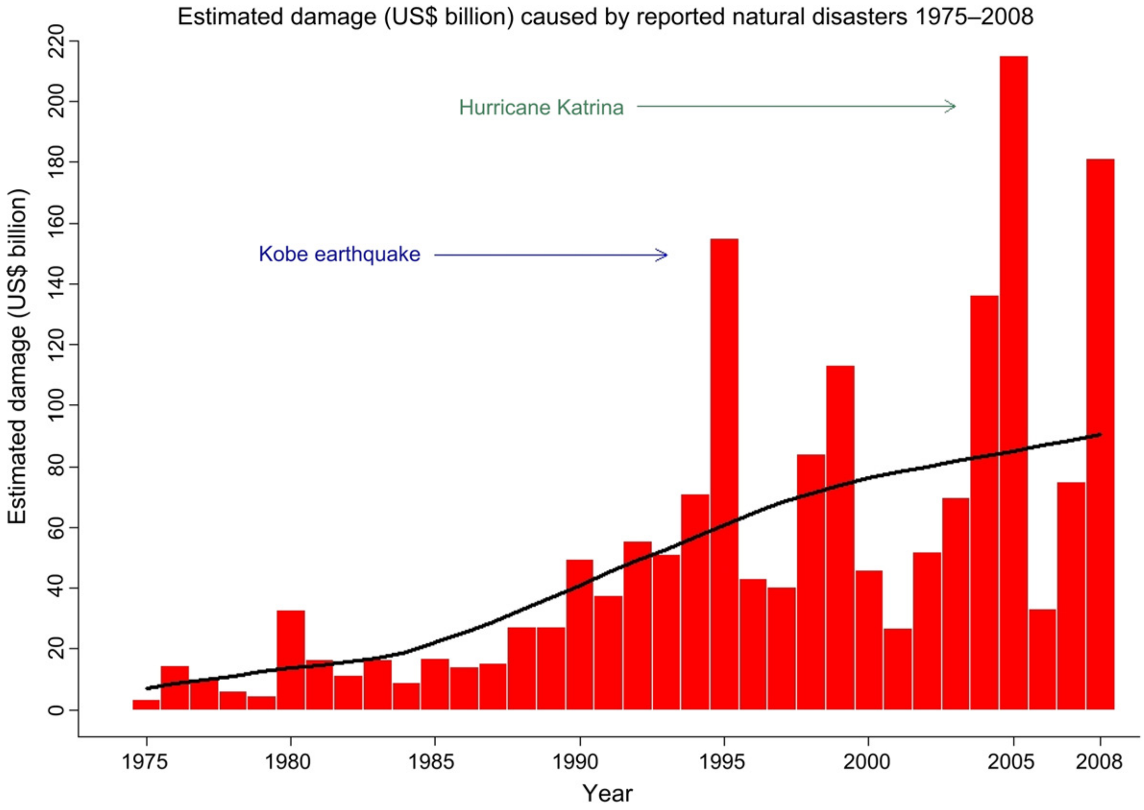

Figure 3 Natural disasters. Source: EM-DAT.

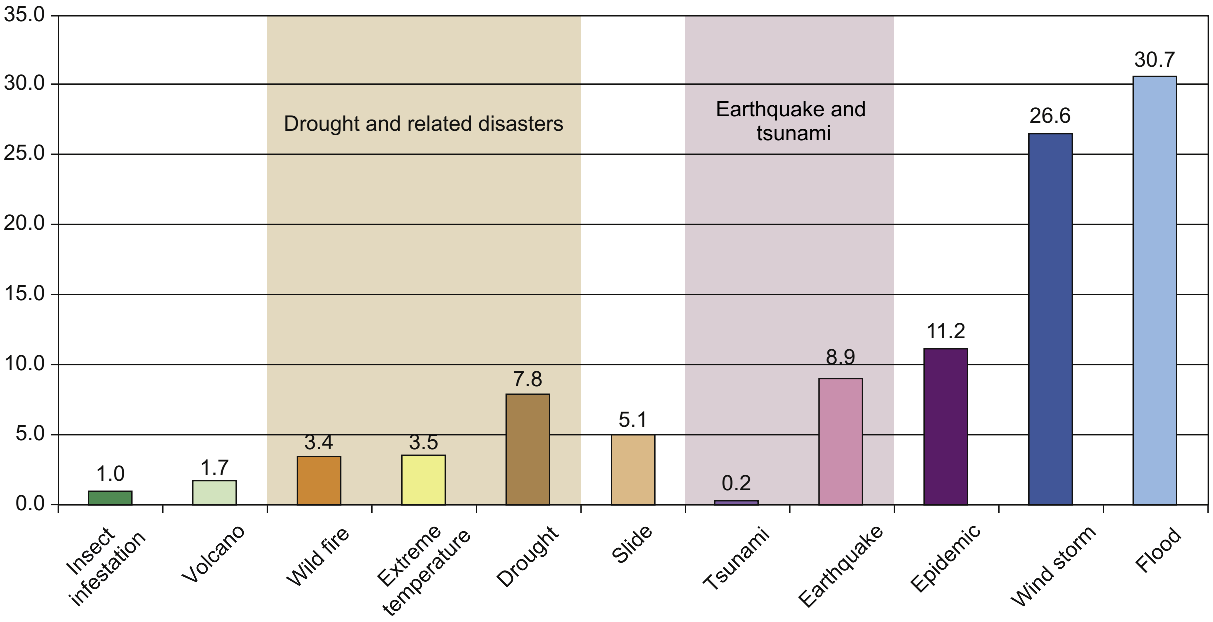

Figure 4 Distribution in percentage of natural disasters by type, 1991–2005. Source: EM-DAT.

Japanese Tohoku–Sendai earthquake, March 2011, are reviewed after the relocation introduction.

Tokyo is one of the megacities of the world, with more than 18 million people. The major problems of Tokyo are the high population density, pollution, and transportation congestion. In addition to these problems, future natural disasters (e.g., earthquakes, volcanoes) have been identified as major problems for the existence of Tokyo.

The Government of Japan (the National Diet) decided in 1992 to 'split' the Tokyo metropolitan area: first, to generate a new satellite city ('Washington, DC') for the Diet, the Prime Minister's Office, the Supreme Court, and other government agencies out of Tokyo (relocation of capital functions); and then for the rest of Tokyo to have a 'New York'-type function as Japan's economic center. The budget of this project was ~$12 billion.

A Council of 'wise men' was generated to find the optimal place for the Japanese 'Washington, DC.' The Council formulated 16 criteria for the new place.

Most of these criteria involved logistics and networking the Tokyo metropolitan area with the rest of the country and foreign countries.

Two environmental criteria were imposed:

1. Harmony with the natural environment
2. The possibility of lessening the environmental load

Furthermore, the following natural disasters criteria have been used:

1. Safety in the event of an earthquake disaster
2. Safety in the event of a volcanic eruption
3. Safety against flood and sediment disasters
4. Speedy response in a large-scale disaster

These disaster criteria might be seen as risk dispersion and resilience increase to disasters. If Tokyo would have a large-scale disaster in the future, the possibility of simultaneous large-scale disasters in the satellite city must be minimal. However, this brilliant project was not approved by the next Japanese government because of land speculation and other political considerations, and the project was neglected.

The Fukushima Daiichi (Fukushima 1) nuclear accident in 2011 revitalized the project once again, but the government must find a new place for the satellite city of Tokyo. The main nuclear accidents before Fukushima 1 were Chernobyl (USSR) in 1986 and Three Mile Island (USA) in 1979.

Fukushima was a multiple disaster:

- Great East Japan Earthquake (magnitude 9.0 R)
- 600 aftershocks (magnitude 5.0 R or greater)
- Tsunami (15 m waves)
- Nuclear explosion

The plant was commissioned in 1971 and had 40 years of operation before the accident. The electrical output was 4.7 gigawatts, and the type of reactor was 'boiling water with containment vessel.' The cause of the accident was that the tsunami destroyed the cooling system of the plant.

What are the effects of this nuclear explosion for the Japanese economy? First, 20 000 inhabitants died or are missing, and >6000 inhabitants were injured. The exclusion zone area in Fukushima is 20 km 1 year after the explosion. The government relocated 350 000 people during the first year. The radiation released in the area was ~400 PBq. Decommissioning will take between 30 and 40 years.

The effects of the nuclear radiation during the decommissioning period on agriculture, water, food, climate, health, and industrial production are impossible to estimate now, although there is some statistical information for the year 2011.

The year 2011 was a significant year in the statistics of natural disasters during the period 1981–2011. The total cost of the natural disaster (buildings, lifeline utilities, social infrastructure, and others) in 2011 was the highest during the aforementioned period, almost ¥17 trillion. The trade deficit of export-oriented Japan was negative in 2011 for the first time in the history of the last 30 years, but the macroeconomic impact in terms of real GDP changes is expected to be much less than after the 'Lehman shock.'

The Japanese government developed reconstruction plans for its sustainable rebirth. The following list describes the actions taken:

- A new 'Reconstruction Agency'
- ¥23 trillion budget in the next 10 years
- Tax incentive system and fiscal health
- Disaster risk reduction
- Disaster relief
- Subsidy to locate industries in Japan
- Reconstruction open to the world (kizuna)
- Additional public infrastructure projects
- Land use restructuring
- Building regions that respond to the challenges of an aging society and disaster reduction
- Promoting the introduction of renewable energy
- Developing disaster resilient information network
- Creating 'eco-towns'
- Supporting small- and medium-sized enterprises
- Testing radiation of export products and rigorous radiation monitoring
- Designing decontamination roadmap for special areas
- Designing roadmap toward decommissioning of Fukushima Daiichi, TEPCO
- Speedy supply chain recovery

Source: National Policy Unit, March 2012.

The future of nuclear plants is presently uncertain in Japan. There are three major issues: (1) How many nuclear plants will Japan have in the future? (2) Will nuclear plants be nationalized? The Fukushima Daiichi was a private power plant managed by the company TEPCO. (3) What will be the optimal ratio of imported electricity to the electricity produced in Japan? There are other dynamics for post-Fukushima Japan as well. The big car companies such as Honda want to move away from Japan to other countries. They consider that Japanese natural disasters can be adverse to their economic future.

3.07.7 A Survey of Sustainability, Sustainable Development, and Sustainability Science

Following the survey of Grober (2007), the authors found out that the SD-definition (nachhaltigkeit) had been minted by German Royal Mining Officer Hanns Carl von Carlowitz in 1713. Von Carlowitz wrote a comprehensive book (~400 pages) of forestry management called *Sylvicultura oeconomica* (1713). *Anweisung zur wilden Baumzucht* dealt with the conservation and cultivation of timber. At that period, timber was a strategic resource like oil is 260 years later.

Sustained yield (*nachhaltigkeit*) was diffused in other parts of the world through the work of Alexander von Humboldt and the 'father of ecology,' Ernst Haeckel. The French translation was production soutenu, soutenabilite, or durabilite, but the word *soutenir* is based on the Latin verb *sustenere* (uphold). The etymology in Spanish is either *sostenibilidad* (from *sostener*) or *sustenabilidad* (from *sustentar*). The first term has the passive explanation (being upheld), and the second a more active explanation (to uphold). Also, the English translation sustainability has the same Latin origin, *sustenere*.

Similarly, the term sustainability in Norwegian is *baerkraft*, in Greek *viosimotita*, and in Swedish *hållbarhet*.

The term *nachhaltigkeit* has been used mainly in German forest management references since its original publication. The English translation became popular in the last decades of the twentieth century by international organizations (e.g., Club of Rome), the European Social Democrats (Olaf Palme, Willy Brandt, and Gro Harlem-Brundtland), and finally by the United Nations' and World Bank's massive research programs.

An earlier environmental work was *The Limits to Growth* (1972). The *Limits* was written by a group of scientists from MIT under the leadership of Dennis Meadows and Donella Meadows. The main purpose was the investigation of the long-term causes and consequences of the finite nature of resources. The main model variables were growth in population, industrial capital, food production, resource consumption, and pollution.

A methodology used on computer programs called Dynamo was based on the theory of System Dynamics of Jay Forrester (1971). The project was financed by the Club of Rome. Their main pessimistic conclusion was that "the limits to growth on this planet will be reached sometime in the next hundred years." But the MIT team also had an optimistic conclusion that under the assumptions of zero population and capital growth it could be possible "to establish a condition of ecological and economic stability that is sustainable far into the future."

The following newspaper headlines appeared in 1972:

"A computer looks ahead and shudders"
"Study sees disaster by year 2100"
"Scientists warn of global catastrophe"

The book *Limits to Growth* is considered the first environmental book in history that had a massive impact and public support (9 million books sold and translated into 30 languages).

Some economists have pointed out that *The Limits* was the theoretical framework of the energy crisis. The reason was that the OPEC countries understood they have great bargaining power in oil price negotiations with other countries.

The Limits was not only important to the discussion about our future, but also mobilized the United Nations and the World Bank to become more active in world environmental issues.

The first UN Conference on the Human Environment took place in Stockholm in 1972. The subject of the conference was the 'nonlocality' or internationalization of lake pollution. Scientists found contamination from pollutants in Swedish lakes from Poland and other Baltic countries. Olof Palme was the representative from Sweden, and he invited Indira Gandhi as one of the main representatives of the developing world. The communication that resulted was not particularly effective between the representatives of the developed and the developing world.

Gandhi stated that "poverty is the worst pollution," and the representatives understood that a big gap existed in the concept of pollution and economic priorities between the developed and developing world.

Furthermore, if we read the conference documents, we find some normative recommendations for the wise use of natural resources. One of the most important recommendations of the conference was the monitoring of pollution.

The then president of World Bank, Robert McNamara, announced the idea of establishing a commission of politicians and technocrats. In 1977, the former German Chancellor and Nobel laureate for 'Östpolitik,' Willy Brandt, became the chairman of this commission – the Independent Commission on International Development Issues (the Brandt Commission). This helped to improve the climate of North–South (developed world-developing world) relations. Olof Palme was a member of the Commission too following his Stockholm Conference experience.

The Brandt Commission published two books: *North-South* (1980) and *Common Crisis* (1983). These books dealt with issues like environment, food, energy, trade, population growth, development, and negotiations.

It is worth mentioning some works related to the environment between the publications of *The Limits* and the Brandt Commission.

The 'World Council of Churches' (WCC) in a world conference in Bucharest (1974) used the term "just and sustainable society."

The World Wildlife Fund (WWF) in cooperation with UNEP and the International Union for the Conservation of Nature (IUCN) published a declaration in 1980 called a "Living Resource Conservation for Sustainable Development."

The UN General Assembly generated the World Commission on the Environment and Development (1983) under the leadership of the Norwegian politician Gro Harlem-Brundtland (GHB). Their work, *Our Common Future* (1987), was published years later. GHB used the previous work of Brandt, WWF, WCC, and Meadows and she was the mother of a new concept: sustainable development (SD).

They defined 'sustainable development' as "development which meets the needs of the present without compromising the ability of future generations to meet their own needs." They continued by pointing out that energy consumption should be more ecology oriented:

Sustainable global development requires that those who are more affluent adopt life-styles within the planet's ecological means – in their use of energy, for example.

In other words, SD is a new development concept and new long-run economic policy. It is an intragenerational and intergenerational comparison of utility or consumption.

The commission made the idea of SD politically acceptable for both developed and developing nations. This was a historical moment for setting the beginning of the unification and communication between different countries of the world.

However, there is a 'scarcity of plenty' definition of sustainability. Solow (1988) has defined sustainability as maintenance of production opportunities or 'certain standards of consumption/living possibilities over time.'

Ecological economics might be a system of knowledge that combines the management of households (economics) with the housekeeping of nature (ecology).

The ecological definition of Eriksson and Andersson (2010) might be:

> An ecological system being sustainable if it is resilient.

Resilience must satisfy these conditions:

- The degree to which the system is capable of self-organization.
- The ability to build and increase the capacity for learning and adaptation.
- The amount of change the system can undergo and still retain the same controls on structure.

The physics Nobel laureate Gell-Mann (2010) gave a new definition:

> … sustainability refers to quality of human life and of the environment that is not gained at the expense of the future.

He continued with the economic transition for sustainability.

> The economic transition must, of course, involve what economists call 'the internalization of externalities'. Prices will have to come much closer to reflecting true costs, including damage to the future.

This complicated price estimation has important energy substitution effects. However, we note that renewable energy technologies might be financially competitive with nonrenewable energy technologies in the future because of research and development as well as technological development.

A more operational definition of sustainable development has been given by IUCN et al. (1991), as "improving the quality of human life while living within the carrying capacity of supporting ecosystems."

In the last 10 years, a new sustainability science has emerged based on the interrelationships between society, the earth, and the post-GHB literature. Some core questions were asked in an interdisciplinary policy forum for the nature of Sustainability Science (2001):

1. What systems of incentive structures – including markets, rules, norms, and scientific information – can most effectively improve social capacity to guide interactions between nature and society toward more sustainable trajectories?
2. How can today's relatively independent activities of research planning, monitoring, assessment, and decision support be better integrated into systems for adaptive management and societal learning?
3. What determines the vulnerability or resilience of the nature–society system, in particular the kinds of places and particular types of ecosystems and human livelihoods?

Sustainability has been a success story for the last 20 years. The number of documents of sustainable development can be estimated at ~21 500 000 as of 2011 (Bettencourt and Kaur 2011).

This statistical evidence of sustainability documents demonstrates that sustainability science has an increased scientific impact and longevity.

3.07.8 The IPCC, the Stern Review, and a Critique of Top-Down Modeling

The IPCC was organized by the joint effort of the United Nations and the World Meteorological Organization (WMO). The main idea behind the IPCC was economies of scale in research by using large international groups of scientists and the increased credibility of the research outcome by the scientific community. The science and knowledge evolution has been based on individuals or small groups (5–12 scientists) throughout history.

The IPCC configuration was a scientific trend of discontinuity. The IPCC groups were composed of more than 1000 scientists in each group, with a flexible time and labor input. Although the IPCC monopolized (or oligopolized) the climate debate during the last 20 years, there is an increasing critique among scientists of IPCC's scientific evidence.

The four IPPC studies on sustainable development (1988–2007) have evolved gradually.

The discussion on sustainable development in the IPCCs has the following dynamics:

The first assessment report (AR1) focused on the technology and cost-effectiveness of mitigation strategies. The second assessment report was broader than the first. The issues were related to equity across countries and generations, as well as environmental and social considerations. The focus was even broader in the third assessment report (TAR), with three classes of analyses or perspectives: efficiency and cost-effectiveness, equity and sustainable development, and sustainability and societal learning. Many IPCC expert group meetings supported the TAR with emphasis on social dimensions of climate and sustainable development.

In the fourth assessment report (AR4) the complexity of sustainable development is more prominent and includes:

- Concept
- Environmental, economic, and social dimensions
- Climate mitigation development choices in a modeling context
- Impact of mitigation options on sustainable developments goals
- International sustainable development policies
- Adaptation practices, option constraints, and capacity
- Interrelationships between adaptation and mitigation
- Adaptation and sustainable development

The essence of this assessment is 'climate first.' Climate first is determined by government-driven, climate-specific measures that impose limitations of GHG emissions. The risks of climate are functions of these measures.

Another interesting issue is the relationship between economic development and climate.

"Making development more sustainable" is a critical balance of environmental, social, and economic dimensions for developing nations. Finally, interactions of state, market, and society can influence the mitigation of climate.

At the end of his political career, the English Prime Minister Tony Blair had the ambition to follow in the footsteps of Willy Brandt and GHB in building a commission to analyze the effects of climate in the new millennium. Finance Minister

Gordon Brown generated the necessary financial resources for this commission, but Blair resigned and Brown became prime minister.

The leader of this commission was Nicholas Stern, a chief economist from the World Bank. Because of the political conflict between Blair and Brown, neither man could give his name to the commission. In 2006, Stern published the research of this commission, the so-called Stern Review.

The Review was based on statistics from TAR, but the economic analysis of the Review was far beyond the TAR analysis.

The main Review conclusion was that the world economy should decrease GNP growth by 1% so as to finance the reduction of GHG emissions toward a sustainable world future. This conclusion generated a lot of reaction by economists and geoscientists, but it was used by the AR4. In other words, sustainability has a monetary cost. Is there any willingness to pay for this sustainability?

The political scientist Roger Pielke Jr. gave an answer in his well-cited book, *The Climate Fix* (2010): "When policies on emissions reduction collide with policies focused on economic growth, economic growth will win every time." Pielke's realistic answer generates limitations for climate policies.

Both the IPPC basic models and the Stern Review model are top-down models.

The difference between top-down models and bottom-up models is outlined below.

In top-down 'socialistic' economic models, the central planner can comprehend the mechanism of the system and is able to calculate the set of optimal prices. The market system is not necessary in this type of model.

If we use top-down (the cathedral) environmental models, we may not achieve policy coherence among national, regional, and local levels. For example, the executive (decision maker) makes a decision, and this decision is disseminated to the lower levels in the hierarchy. The economist Oscar Lange used the Soviet economic planning system as a typical example of the top-down approach.

The bottom-up model can achieve better policy coherence among national, regional, and local levels on environmental and energy issues. Nobel laureate Hayek (1945) described the bottom-up model with the use of the market system (bazaar). Individuals cannot understand the information complexity of the market, although they can understand partial information bits.

The role of the markets is the aggregation process of information. In managerial decision making, the bottom-up organization is the one that functions from the grassroots. The information direction is from the inferior to superior.

The top-down versus bottom-up debate migrated from economics to other fields, for example, regional science, environmental studies, architecture, software engineering, public health, and atmospheric science.

In computer science, a successful application of bottom-up thinking is the program Linux. The father of Linux was the Finish computer scientist Linus Torvald, who decided to have open-source software with a free 'source code.' This noncommercial, nonproprietary, and collaborative approach is more successful than the top-down and the protected Unix software.

The Nobel Prize in Economic Science in Memory of Alfred Nobel (2009) of Elinor Ostrom was very radical. The Royal Swedish Academy of Sciences cited Ostrom's work "by showing how common resources – forests, fisheries, oil fields or grazing lands, can be managed successfully by the people who use them, rather by governments or private companies."

Her Nobel prize lecture was called, "Beyond Markets and States: Polycentric Governance of Complex Economic Systems."

Two comments for this prize can be written here:

1. Ostrom was the first environmental social scientist to win the Nobel Prize in Economic Science since its inception.
2. Her polycentric governance of commons was based on self-organization and the bottom-up approach.

New paradigms in mathematics, such as complexity theory and fractal geometry, changed the notion of traditional dynamics (Sarafoglou 1994). The path-breaking works of Thom, Lorenz, Mandelbrot, and Prigogine left footprints in the "idea of control from the bottom-up came onto the agenda." The urban geographer Michael Batty (2005) wrote that "the notion of smooth change was quickly abandoned as ideas concerning catastrophe theory, bifurcation, chaos came onto agenda. The notions of systems being far-from-equilibrium took hold. The notion of positive feedback is essential to these dynamics."

The Santa Fe Institute was an important intellectual hub for the implementation of path dependence and bottom-up system evolution, but the superstructure of this evolution is now much bigger.

3.07.9 Future Studies in Energy

The famous Danish physicist Niels Bohr said, "Prediction is very difficult, especially about the future." In the past, very few authors could predict the future with high accuracy.

Jules Verne in the late 1800s (urban life, astronaut mission, and deep sea), Leonardo da Vinci in the late 1400s (airplane, helicopter, and adding machine), and the 'noir prophet' William Gibson (World Wide Web) in his *Neuromancer* (1984) were the most famous authors.

There are some certainties for the future energy market, such as the gradual transition from nonrenewable to renewable sources and the increased efficiency of energy use.

Table 1 Energy futures during the period 2012–2100

Near future (2012–30)
Solar power, wind power, hydrogen, electric car, nuclear fission, improved internal combustion, alternative fuels, storing sunshine, capturing carbon, solar-thermal engine, microbial fuel cell, better bioreactors, and artificial photosynthesis.
Mid-future (2030–70)
Pollutants into the atmosphere, algae blooms, carbon sequestration, genetic engineering, fusion power, hot fusion, fusion by laser fusion in a magnetic field, tabletop fusion.
Far future (2070–2100)
Magnetism, the magnetic car and train, space solar power

Source: Scientific American, 2012: Scenarios for a Clean Energy Future, March 11; and Kaku, M., 2011: *Physics of the Future*, Doubleday.

We do not know the spatiotemporal information and the most dominant form of energy of the future, but we should speculate for the energy forms of the near, mid, and the far future (Table 1).

Finally, will we have an energy crisis in the future?

Can scientific progress solve the increased energy demand problem?

Can the world leaders increase their efforts to accommodate new forms of energy?

The Greek politician Perikles (fourth century) had a pragmatic view of the future, "It is not important to know the future but rather to be prepared for it."

3.07.10 Conclusions

Deffeyes (2006) wrote, "It will be more orderly if we were to generate a blueprint for a society constrained by the availability of resources. Then we need a noncatastrophic pathway that takes us from here to that blueprint. Welcome to the post-Hubbert world, the world beyond oil."

In the post-1973 energy crisis period, two main energy infrastructure trends for the decarbonization of energy have been observed:

1. A temporal increase of energy efficiency (or the dynamic efficiency) through technological improvements and substitution from nonsustainable (nonrenewable) energy to secure sustainable (renewable) energy is possible through carbon taxes.
2. Dynamic efficiency can reduce the supply energy, and the substitution can reduce energy demand; this energy substitution might be more quantitative and qualitative in the future.

Our conclusions for the sustainability paradigm of energy infrastructure are as follows:

1. The Brandt Commission and GHB Commission's conceptual framework for the North–South equity relations should be continued and be applied for the energy infrastructure and the energy poverty (Kash et al. 1976; Lovelock 2006; Schellnhuber et al. 2010).

   The climate is a local, national, and global issue, and the cooperation of all nations is critical for reduction of GHG emissions and natural disasters. Sustainable development is one of the most important goals of the twenty-first century and one of the Millennium Development Goals (MDGs). The year 2012 has been declared by the United Nations General Assembly as the "International Year of Sustainable Energy for All." The main commitment of the Secretary-General's vision is "Sustainable Energy for All will revitalize the global economy, improve social; equity and protect the ecosystems which support all life. Children will be able to study after dark, hospitals and health clinics will function properly and nations will be more energy secure."
2. The systems approach is essential for infrastructure interrelationships; for example, the energy infrastructure price structure can change the price structure of the transport infrastructure and the building infrastructure and vice versa. The symbiotic dynamics of energy, transport, and building infrastructures within the existing planetary boundaries can be assessed by systems analysis.
3. Population dynamics (growth, urbanization, and aging) can influence the dynamics of energy infrastructure. At IIASA in Laxenburg, researchers use multistate demographic models for forecasting the size and composition of the world population in the year 2050, and the economic effects of different spatial population distribution scenarios such as megacities. The environmental maintenance of the aging society is another major issue.
4. The increased implementation of the sustainability paradigm in the future energy infrastructure might be the best method to decrease the environmental and health problems of this century. The estimated share of the world's nonsustainable energy infrastructure was 84% in 2010. In other words, we have a long way to go to increase the share of sustainable energy infrastructure in the world and minimize energy path dependence (Mansson 1993; IEA 2007; Hochrainer 2009).
5. A new integrated Ministry of Energy and Environment (MEE) should be generated in every nation for low-carbon prosperity. All environment-related questions (taxes, investments, demand management, and other policy variables) will be concentrated in this ministry. Achieving policy coherence among national, regional, and local targets or applying more bottom-up and less top-down perspectives is critical for the energy sector. MEE could achieve better efficiency and efficacy of national energy and environmental policies for a sustainable future (Nordhaus 1995; Silveira 2001; IPCC 2007; MacKay 2010).

The Russell–Einstein Manifesto (1955) is a historical document signed by 10 Nobel laureates for the perils arising from the development of nuclear arms in the Cold War era:

> In the tragic situation which confronts humanity, we feel that scientists should assemble in conference to appraise the perils that have arisen …

We may need a new and revised Russell–Einstein Manifesto and a 'grand unified theory of sustainability' for inspiration and scientific guidance of modern energy and environment–climate complexities.

Notes

1. The definitions of risk and uncertainty are overlapping in the disaster literature.

   Frank Knight's differentiation (1921) of risk and uncertainty in economics has been ignored. According to this theory, risk can be expressed in terms of probabilities in a stochastic decision-making process. On the contrary, uncertainty cannot be expressed in terms of probabilities.

   There is a misperception of risk in terms of underestimation of probability and costs of a disaster. This misperception leads to the lack of interest in mitigation and risk management strategies.
2. Fukushima means 'good luck island' in Japanese. Fukushima Daiichi means 'good luck island number one.' In this

we refer to the Fukushima Daiichi nuclear power plant. There is also a plant called Fukushima Daiini (Fukushima number 2) nearby. Fukushima Daiini did not have any problem with the tsunami.

3.08.1 Introduction

In the energy sector, climate information can play a strategic role, particularly in hot spot regions such as the Mediterranean region. In order to limit GHG emissions, within the European Union (EU) framework there will be opportunities for trading renewable energy quotas among member states and to gain credit for electricity imported from renewable sources in countries outside the EU (Komendantova et al. 2012; Club of Rome 2008, http://www.clubofrome.org/eng/home/). This framework will trigger new, strong interaction between climate information providers and energy sector stakeholders. The basic assumption of this perspective, of course, is that a prediction of climate on multi-decadal time scales is attainable.

Such trades are also envisioned in initiatives such as the Mediterranean Solar Plan (MSP). The goal of the MSP is to generate 20 GW of new power production capacity based on renewable energy (photovoltaic, wind, and CSP (concentrated solar power)) in the Mediterranean by 2020. This will contribute to energy efficiency in the region and states, institutions, firms, and investors from Northern and Southern Europe will be involved in a common industrial project with high potential of economic growth and employment.

An even more ambitious plan for renewable energy, known as the Desertec Industrial Initiative (DII, Knies et al. 2008), was announced by a consortium of German investors in July 2009. The DII has a target of generating €440 billion in investments on CSP in North Africa largely for export to Europe. The Mediterranean energy plan is of paramount importance at the European level in order to transform the EU into a low-carbon economy with strong competition of internal markets and an improvement of supply security and employment prospects. In addition, renewable energy sources will play an important role in responding to climate effects over the region.

For example, enhanced use of solar power could address the increasing energy demand for summer cooling and, along with wind energy, provide the energy source to power desalinization plants needed if the Mediterranean area becomes more arid. The European goals for 2020 include reducing GHG emissions from all primary sources by at least 20% with respect to 1990, increasing the share of renewable energy sources (RES) by 20%, and improving energy efficiency by 20% (the European 20-20-20 target).

How climate information can be useful for specific energy sectors depends on the development of a strong interaction between energy producers, energy managers, and climate experts. This interaction is a fundamental step toward a decarbonized society. The primary goal of climate services for the energy sector is thus to develop a design, research, and communication protocol by which climate information is transferred from the science realm to the stakeholder application realm in order to develop suitable adaptation measures.

The most innovative aspect in the development of this climate services framework will be its bottom-up approach, by which stakeholders are to be involved in the design of the services from its early stages in conjunction and strong communication with the science community and the climate information providers (e.g., national and international climate services centers, meteorological centers).

3.08.2 Climate Services Framework

Increasing the quality, reliability, and detail of climate information for societal use has become a major challenge in regions whose economic growth and social development crucially depend on adaptation to climate variability and longer-term trends. In this regard, the Third World Climate Conference (WCC3) put forward a strong recommendation for the development of a global network of Climate Service centers (Mr. Michel Jarraud, Secretary-General of the World Meteorological Organization – WMO, WCC-3, 2009).

> "by boosting the observations and research we have available for monitoring the climate and then facilitating the creation of sector- and regional-specific products and services that will be readily available to all who need it."

An effective exchange of information between the science and stakeholder communities is especially important for regions that are particularly vulnerable to climate variability and longer-term change. Therefore, more than 2000 scientist

http://dx.doi.org/10.1016/B978-0-12-384703-4.00317-8

during the WCC3 conference set up the Global Framework for Climate Services (GFCS) with the aim of strengthening the production, availability, dissemination, and application of prediction of climate science and services. Its objective is the development and provision of scientific information and climate predictions for risk management for adaptation to climate. One challenge, of course is whether skillful predictions of changes in climate statistics on the multi-decadal time scales can be attained. A major requirement for the GFCS should be to assess the predictability of changes in climate statistics on the time and space scales needed by stakeholders.

The GFCS has four main elements. In addition to climate research, observation, and monitoring, the real novelty of this initiative is represented by the mechanism of interaction with users User Interaction Mechanism (UIM) system and the World Climate Services (WCS) system. In fact, the center's mission for the GFCS are increasing and improving interactions between service providers and users of the climate information.

The fisheries, water, health, forestry, transport, tourism, and energy sectors are increasingly concerned with climate risks, but the decision makers involved in these sectors are not always culturally ready to assimilate the available climate information and apply it. The needs of the user community are diverse and complex. A close interaction between scientists and experts from other fields and disciplines is essential to focus on the specific requirements of different users.

Adaptation capacity depends on the structural link between energy sector infrastructures/activities and climate, on the time scale of the climate–energy link, and the development of a strong interaction between climate information providers and energy sector stakeholders. The base time horizon of interest in the energy sector ranges from seasonal to decadal time frames and from present climate information to the entire spectrum on plausible future climate conditions.

This is the time horizon of greatest interest for the assessment of impacts and the development of adaptation measures. It includes the contributions of both natural climate variability (especially in the early decades), GHG-forced climate change (especially in the latter decades), and other human drivers such as land-use change (Pielke et al. 2009; Anav et al. 2010). It will place climate services framework within the newly emerging field of decadal climate prediction, which will allow for the potential of a strong novel contribution. The spatial scale of interest for climate services' framework will be regional (e.g., catchment basin) to local (e.g., city level). This can be achieved through the refinement and development of new dynamic and statistical downscaling tools, although caveats have been highlighted (Pielke and Wilby 2012). We do stress, however, that although the temporal and spatial scales of interest are as stated above, the actual ones will be dictated by the stakeholder needs involved in GFCS framework.

Finally, an important focus of the climate services framework will be on the development of, and provision of training for, a new research expertise lying at the interface between the science results and the stakeholder application. To date, the communication between the science and application communities has been sorely lacking, partially because of the widely different perspectives across them. Even within the Intergovernment Panel on Climate Change (IPCC) process there is still a stark divide between the science (WGI) and the application segments (WGII and WGIII). A new expertise is needed which can more fully integrate the needs and transfer of information between these communities without a preconceived perspective.

3.08.3 Potential Climate Impact on Energy Production

Ernst & Young, in their conceptual framework, place the crossover point between costs and margins for renewable energy in 2012–13 (*Renewable Energy Attractiveness Indices* Issue 27, 2010). In most of the Western countries, renewables are now transitioning from the stimulus to the poststimulus phase. Nevertheless, in recent months the removal of subsidies is balanced by the Fukushima effect. The health of the general economy continues to have a major effect in driving renewable energy. However, climate-related issues begin to have an important role in planning and managing new renewable plants. Here, we summarize key energy sectors in which the use of climate information becomes more and more important. We do not intend to provide a complete listing of sectors and of climate-related parameters, instead we would like to introduce some examples that could be potentially viewed as benchmark case studies (special emphasis on Power Grid as an emerging issue for green energy) in the context of the climate services framework.

Table 1 is a summary point for identifying the needs for climate data in addressing the various fields of application of the energy sectors. To understand the requirements of climate products and services for energy management, one only needs to look at the trends in the analysis of climate information in support of energy activities.

3.08.3.1 Power Grid

Electricity demand is dependent on temperature, owing to the use of residential and industrial HVAC (heating, ventilation, and air conditioning) equipment, refrigeration, and irrigation. During winter or summer periods, a small change of average temperature can lead to a significant variation of electricity load, especially on particularly warm or cold regions. Trends in extreme weather and climate events (e.g., heat waves, storms, snowstorms) will strongly affect these aspects of the power grid. To give an example, Figure 1 describes the relationship between average temperature and average load on a daily basis in Italy; this analysis has been performed using data provided by TERNA, the Italian transmission grid operator, considering the period 2003–09. We can observe how intensively the average temperature affects the electricity demand during the entire year, fitted with a 2nd order polynomial, and then in particular during the summer period when the electricity demand is strongly influenced by the needs of refrigeration and ventilation equipments. Similar behavior is observed on other Mediterranean countries, like Spain and France, with the respective energy demand data (see Valor et al. 2001, for a study on Spanish electricity loads).

For this reason, in order to avoid power outages and the consequent negative impact to customers, it is important to prevent critical situations using a load forecasting model with

Table 1 Basic climate information needs of the energy sector

			Type of climatological input data	
Field of application	*Energy element needed*	*Climatological element needed*	*Time scale*	*Space scale*
Power Grid	Daily load and network structure	Air temperature	d, m	g, a
Gas production and distribution	Network structure	Precipitation	h, d	g, a
		Air temperature	d, m	g, a
		Wind speed	d, m	g, a
Wind	Production – high resolution time series	Wind	h, d	s, g
		Pressure	d, m	s, g
Solar	Production data	Radiation	h, d	s, g
		Wind	min, max	s, g
		Temperature	d, m	s, g
		Humidity	d, m	s, g
		Clouds	h, d	s, g
		Aerosols	h, d	s, g
Hydropower and water-based cooling systems	Production data	Temperature	d, m	s, a
	Plants temperature	Rainfall	d, m	s, a
		Runoff	d, m	s, a
		Water level	d, m	s, a
		Snow cover	d, m	s, a
		Snow melt	d, m	s, a
		Soil Moisture	d, m	s, a
Marine energy	Production data	Wind	d, m	s, g
		Wave height and direction	d, m	s, g
		Current speed	d, m	s, g

s = point values; a = areal values; g = grid values; y = annual values; m = monthly values; d = daily values; h = hourly values; min = minimum values; max = maximum values.

accurate weather models as inputs. An accurate forecast can give precious information both on short (from minutes to days) and long (from weeks to months) time scales, allowing an effective and efficient operations management and power dispatch for electric utilities. Finally, the definition of plausible climate scenarios is of critical importance for planning on both the supply-side (i.e., creation of new power stations, transmission lines expansion, and effect of climate on renewable-energy generation) and the demand-side (i.e., influence of climate on energy demand).

Another aspect that would increase the effects of climate on power grids is the global migration of populations toward

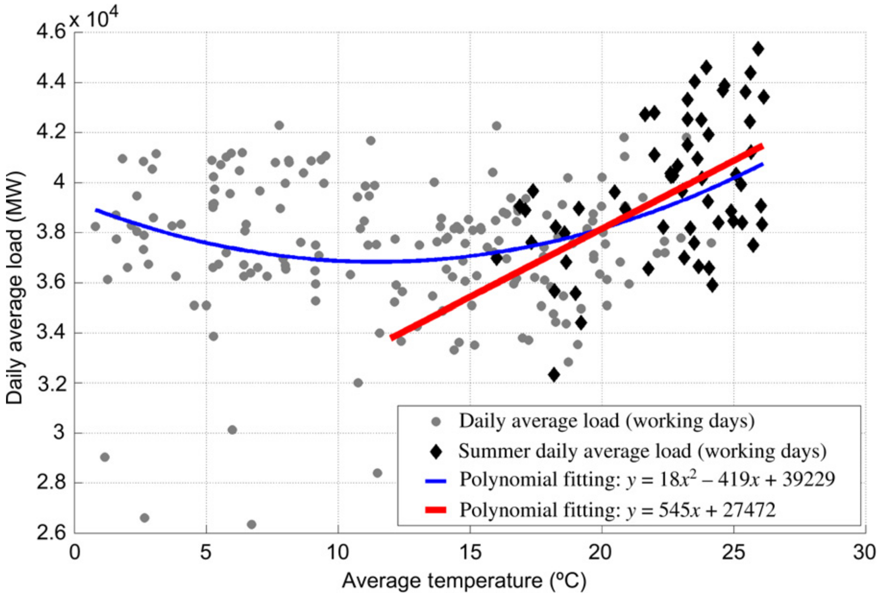

Figure 1 Relationship between air temperature and daily load in Italy during the years 2003–09.

urban areas; in fact by 2040 more than the 60% of world population will live in urban areas (United Nations, Department of Economic and Social Affairs, Population Division 2009). Predicting and providing the electricity demand of larger cities will become more and more important during critical events like heat waves: an example of such an effect has been observed during the 2006 heat wave in North America that caused power outages in many densely populated areas, like Southern California and New York City. Moreover, temperature also affects the operation (and maintenance costs) of high-voltage transmission lines; in fact their operation is strongly affected by extreme weather events (heavy rain, icing, lightning strikes, storms, cold snaps). In the case of interruptions, it is critical for transmission grid operators to balance the grid with different methods: with generation response mechanisms (pumped storage or reserve power stations), asking to the distribution network operators to lower the demand, and using electricity interconnections with neighbor countries.

Another aspect that must be taken into account is the influence of temperature on transmission capacity; in fact the ambient temperature affects the conductors' resistance and, consequently, power losses. Moreover, when a power line heats up for both heavy load and hot weather, it stretches and sags with the possibility to hit nearby objects or vegetation, causing a short circuit and line disconnection.

A discussion about the influence of weather and climate on load forecasting and, more in general, on the energy industry can be quite relevant in vulnerable regions such as the Mediterranean.

3.08.3.2 Gas Production and Distribution

As many winter examples demonstrated, European countries depend on the reliability of eastern and southern gas supply (Russia, Algeria, etc.). Europe is connected to other world regions via pipelines. The length of these pipelines amounts to several thousand kilometers operated under different climate conditions. The global warming increases the probability of extreme events (heavy precipitation, heat waves, wind storms). Climate information is of considerable importance and widely used in the gas industry. Based on the analysis of Russian industry (Troccoli 2010), the natural hazards in the accident rate amount to about 8%. An important component for risk assessment and for the prevention of accidents is the improvement of climate information of the atmospheric extremes, which are used for engineering solutions and protection of facilities.

3.08.3.3 Wind

Wind power has unique characteristics with its output varying greatly and within short periods of time. Wind variability cannot be completely controlled or predicted. Consequently, an increasing wind market share puts pressure on the electricity grid system and its innovative management. It is widely recognized that as the wind market increases, there will be a greater need for compensating sources that can support its irregular character (Vos 2012). This research featured natural gas as the best-suited generation fuel to support an increasing wind market.

With great expectations placed by Germany and the United Kingdom among others, on a significant offshore wind expansion to meet their 2020 targets, and with tens of billions of euros envisaged to build next-generation offshore infrastructures, wind energy would become a viable and reliable part of the energy mix. With high-power wind turbines (up to 5 MW) placed at about 100 m high for marine use, wind information needs to be much more accurate considering all statistical moments of the wind and the shape of distribution that are required. Detailed information at high resolution has a relevant economic value for planning new wind farms. Considering long-term climate trends and variability, changes in atmospheric teleconnection patterns (for instance NAO) would influence the wind statistics of specific regions, such as the Mediterranean, influencing the number and strength of storms, and in turn impacting on renewable-energy production. Therefore, climate is an issue for renewable energy, with respect to the payback period in capital budgeting and insurance planning.

Wind farms could be a very good example and benchmark for evaluating reliability and use of climate information. The availability of wind energy production data and of wind farm models allows us to analyze the link with wind variability. The production of high-resolution wind data down to scale of a wind farm and for a long period, long enough to be used as a statistical reference, is a challenge for the climate services framework. Many climate impact analyses, including those focused on wind energy, use individual climate models and/or statistical downscaling methods rooted in historical observations (Rassmussen et al. 2011).

3.08.3.4 Solar

With over 17 GW installed, Germany leads this market in terms of capacity. Spain has the second highest solar capacity with about 4 GW installed. North African countries have a significant solar potential (around 1700–2200 Kw m^{-2} per annum). The Mediterranean countries are able to support CSP and photovoltaic (PV) plants on a large scale. In the field of PV and CSP, environmental information that is lacking for sound financial assessment and planning concerns the variability of aerosols and dust in the atmosphere. Dust affects production by thin film deposit on mirrors and modules. Aerosols in the atmosphere dramatically affect the productivity of CSP (Murphy 2009), which is based on direct net irradiation (DNI); other parameters, such as dew, frost, and snow, can be also relevant. Both present weather reanalysis products and plausible future changes in these weather variables taking into account aerosols information are relevant for solar planning.

3.08.3.5 Hydropower and Water-Based Cooling Systems

Hydropower is a well-established and mature technology. Three main types of hydro schemes are in use: storage schemes, with a dam impounding water in a reservoir and using turbine(s); run-of-river using natural flow of a river; and pumped storage with two reservoirs for pumping water from the lower to the upper one. All these hydropower plants have a strong dependence on climate in terms of rainfall and temperature. For instance EDF (Électricité de France, the second largest French energy company) analysis suggested a difficult future for hydropower on Pyrenean catchments owing to rainfall shortage, with average energy production reduced by 20% in the period 2015–45 (respect to 1973–2004) and with highly interannual variable hydroclimatic conditions (Fai et al. 2011).

Rainfall is not the unique relevant parameter. The 2003 heat wave in France featured high air temperatures, as well as warmer river water temperatures used for cooling nuclear power plants as a key parameter for plants management. Higher probability of extreme warm events can result in hundreds of million euros in global costs for the energy sector. Energy groups deserve particular attention to climate variability and longer-term trends, and they are developing action plans, including cooling system design modifications, and improved understanding of the impact of climate on facilities.

3.08.3.6 Marine Energy

Concerning the potential of extracting energy from the sea, new technologies are emerging, especially wave and tidal energy extraction. South Korea's first tidal power plant began full operational in 2011; with an output capacity of about 250 MW, it is now the largest in the world. Long-term feasibility studies are looking at about 1 GW capacity in Korea. Ocean currents and waves are the most important parameters to evaluate for these infrastructures. Both have a strong link to the wind and its variability. Climate variability and longer-term trends can affect the distribution and strength of storms, which in turn influence wind and waves variability. High resolution data of ocean currents for a sufficient number of years (10–20) can be very useful for planning new infrastructures.

All these examples show that detailed climate information has a potential economic value in the energy context. Because of decreased feed-in tariff and to a drop-off in loan guarantees, operative margin will decrease, which in turn increases the relevance of detailed climate information in order to maximize production and to reduce excess margin of safety. Therefore, reliable regional and local estimates of trends in climate parameters in the regions of the highest risk (hot spots) will allow enhancing the quality of planning and design work and safe operation of facilities under construction.

A challenge for the future is for the climate community and the energy community to work together to span the temporal and spatial gaps and to define adaptation measures. A first step should be the identification of requirements, defined, for example, by:

- an assessment of the impacts of climate on a set of different types of projects and plans
- development of methods, standards, and procedural guidelines for impact assessment and climate adaptation
- production of guidelines for integrating impact assessments into planning at the local level and triggering a bottom-up approach for climate adaptation

3.09.1 Energy Market Overview

Over the last 15 years, the US electric industry has undergone fundamental changes that have dramatically changed the way power is produced, transported, and consumed. The industry has moved from a cost-based regulation to competitive market structures. The restructuring of the US electric utility industry is the most massive and complicated industrial reorganization ever attempted in the history of the world. In terms of sheer size (i.e., revenues affected), it dwarfs all of the prior industries restructured either in the United States or abroad, whether telephone, natural gas, railroad, airline, or motor carrier. In terms of complexity, it affects the overlapping regulatory jurisdictions of three nations and more than 55 state, provincial, or other governmental agencies, and by all measures it is unprecedented.

The energy markets in the United States are regulated by the Federal Energy Regulatory Commission (FERC), an independent agency administratively housed within the Department of Energy. FERC regulates wholesale electricity rates, approves transmission line projects, and sets transmission rates. However, FERC's authority is limited in important respects:

1. For the most part, FERC's ratemaking and transmission authorization authority is limited to IOUs in the 48 contiguous states outside of ERCOT, Texas. The entities, which eventually formed ERCOT severed nonemergency connections with outside grids in August 1935. Their objective was to avoid falling under the ratemaking jurisdiction of the Federal Power Commission (FERC's predecessor) by maintaining a purely intrastate system. D.C. ties between ERCOT and the Eastern Interconnection were constructed in the 1980s, but these do not put ERCOT under FERC rate jurisdiction due to a specific exemption in the law (Cudahy 1979).
2. While FERC must approve transmission projects proposed by jurisdictional utilities and establishes rates, a project also needs a siting permit from every state the line will traverse.

Another aspect of FERC regulation is its efforts to encourage competition in the electric power market. In 1996, FERC mandated 'open access' to the transmission system (FERC Orders 888 and 889). Open access requires transmission owners to make available, at cost-based or market-based fees, transmission capacity to any generator or power buyer that is or can be connected to the system.

The objective is to prevent transmission owners from using their control of the power system from stifling competition. To further facilitate open access, in 1999 an FERC order encouraged the creation of the Regional Transmission Organization (RTO). Figure 1 illustrates the current RTO in the United States. The RTO can take over operation of the transmission network in a region or large state, although utilities continue to own their systems. The RTO ensures open access to the grid, operates the energy markets, coordinates transmission planning, and establish mechanisms to pay for new transmission lines (FERC Order 2000).

The RTO manages markets for energy, transmission, and ancillary services. From the viewpoint of standard economic theory, wholesale markets for electricity are inherently incomplete and imperfectly competitive. Some incompleteness is inevitable because power is a flow (or field) of energy that cannot be monitored perfectly and storing potential energy is expensive and in massive scale still illusive. Also, flows on transmission lines are constrained continuously by operational limits and environmental factors, and ramping rates of generators are limited due to physical constraints. The primary cause

[Available online at http://www.ferc.gov/legal/maj-ord-reg.asp.]

is variable demand that presently is almost unresponsive to spot pricing at the retail level for all, except for large industrial customers. Devices for continual control and metering are feasible. Innovative tariffs and service plans have been introduced on small scales, but implementation was slow before liberalization and paradoxically, often retreated after liberalization. In the long run, imperfect competition in power markets stems from the same factors as in other industries, such as economies of scale and other entry barriers, and oligopolistic ownership. Competition is imperfect in intermediate time frames, because production is capital intensive and construction delays are long compared to variations in supply and demand conditions. Competition is inherently imperfect on short time scales because of technical rigidities and physical constraints on the supply side and the inelastic nature, to a large extent of the demand side.

These problems specifically associated with power require strenuous efforts to muster sufficient generation sources and transmission capacity to supply predicted and then actual demand, supplemented by reserves to meet contingencies. The RTO plays exactly this role. There is presently no standard organization of liberalized wholesale markets for power. Every jurisdiction uses a different structure of regulation, governance, system management, and markets. One way to place these various structures along a single dimension focuses on degrees of reliance on market processes, as compared to managerial discretion. This dimension reflects differences in the extent of unbundling of energy, transmission, and reserve capacity into separately priced commodities, and differences in the priority assigned to enhancing coordination. Along this dimension, the organizational forms span a spectrum between two extremes (Wilson 1998).

One extreme assigns broad authority to the operator, intending to recapture advantages of tight coordination obtained previously from vertical integration. Currently, all the RTOs in the United States follow this market structure. We call this market structure an 'integrated market structure.' The other extreme form is more decentralized, because the operator's responsibility, beyond managing transmission, is to facilitate private markets for other products. For instance, the operator allocates transmission access, but also it auctions tradable transmission rights and ensures joint feasibility of the participants' operating schedules. In this model, separating markets for energy, transmission, and ancillary services sacrifices tight coordination, but intends to maximize the role of private markets. We call this market organization an 'unbundled market structure.' Most of the operators in Europe follow this market organization, with a few exceptions, such as Poland and Greece.

If power market were complete and perfect, both market structures could obtain the same result. This is the primal–dual equivalence of first–best implementations, when vigorous competition makes the first–best incentive compatible. Departures from this equivalence differ for the two designs. Integrated market systems start from the premise that gains will be realized from tight coordination in daily operations, and potentially from longer-term obligations and subsidies aimed at strengthening overall reliability. Unbundled market systems start from the opposite premise that participation is voluntary, with no long-term obligations other than a general tariff approved by the regulator. Competing forward markets are encouraged to the extent feasible. The necessity of a system operator with exclusive authority to manage the public good represented by the transmission system is acknowledged. The operator's responsibilities include real-time operations that protect system reliability, but its authority to intervene in forward markets is limited to cases where prior commitments promote reliability, such as day ahead scheduling of transmission.

3.09.2 Key Energy Market Models

Over the last 15 years, the key elements of liberalized energy market have been developed and implemented in many jurisdictions. They include provisions for competitive wholesale markets for energy, an open-access transmission system managed by a system operator (RTO in the United States or Transmission System Operator (TSO) in Europe), and competitive retail markets, leaving the regulated utilities with responsibilities for distribution and a universal service obligation as the default provider, procuring supplies as needed in wholesale markets.

As we discussed in Section 3.09.1 Energy Market Overview, all the RTOs in the United States follow the 'integrated market structure' model. Specifically, all the RTOs run forward and real-time energy markets, ancillary services, and transmission markets by optimizing a Security Constrained Unit Commitment (SCUC) and a Security Constrained Economic Dispatch (SCED) with Locational Marginal Prices (LMPs) derived from shadow prices on system constraints. On the other hand, the TSOs in Europe follow the 'unbundled market structure' model. Specifically, the TSO allocates transmission, procures reserves, and conducts the real-time balancing market to protect reliability while a separate Power Exchange (PX) manages forward markets for energy–although other market-makers could compete with it. The reliance on clearing a sequence of simple markets is the key ingredient of these unbundled markets. In the remainder of this section, we briefly present the most prevalent energy market architectures currently in operation.

3.09.2.1 The Bilateral Energy Model

The bilateral model is motivated by the concept that free market competition is the best way to achieve competition in an electricity market. In this model, suppliers and consumers independently arrange power transactions with each other according to their own financial terms. Economic efficiency is promoted by consumers choosing the least expensive generators. This model might be an obvious choice if a commodity other than electricity were being traded. The special characteristics of electric power networks introduce two problems that have to be addressed in this model. The first problem relates to the presence of transmission constraints, which requires that there exist some form of coordination to maintain system security and make the most efficient use of the constrained transmission system's capacity. The second problem relates to transmission system losses. The treatment of losses is outside the scope of this chapter, but is generally well understood. Both of these problems may be considered as externalities, which have been internalized in the dispatch process in the past. In addition, other ancillary services must be provided to secure the transfer of power from suppliers to consumers (Singh et al. 1997; Singh and Papalexopoulos 2001). These too are outside the scope of this chapter. The resolution of these problems requires a centralized system operator (RTO or TSO) to manage the transmission grid and ensure the security and reliability of the system.

3.09.2.2 The Pool Energy Model

The pool model is motivated by the concern to accommodate the special characteristics of electric power networks within the electricity trading process. The locational aspects of the pool model can be accommodated using a zonal transmission model (Singh et al. 1998), or detailed nodal transmission representation based on the theory of Nodal spot pricing (Schweppe et al. 1988). This model relies on the actions of a system operator for receiving price and quantity offers from generators and demand, selecting the most efficient sources of supply to satisfy prevailing constraints, and making financial transactions that involve payments from consumers and payments to suppliers. The prices that govern these payments are based on the bids submitted by market participants and adjustments made by the system operator to reflect the locational value of suppliers, in terms of their contribution to system losses and constraints. Both models deploy a SCUC bid-based optimization algorithm to clear the market, but they differ on the level of transmission representation that is part of the optimization. Hybrid architectures that combine key elements of both models are also possible.

In the following two sections, we present the market architectures of the zonal and the nodal models. In Section 3.09.5 Transmission Rights Models, we present the basic design of various alternative transmission rights markets that are required to provide hedging to energy market participants.

3.09.3 The Zonal Energy Market Architecture

3.09.3.1 Introduction

In this section, we present a brief description of the zonal energy market architecture.

The zonal model is a compromise between an unconstrained energy pool and the nodal model, where a detailed transmission network is part of the market clearing. In the case of an unconstrained energy pool, no network model is used. In the zonal model, a zonal network model is necessary. This model can be as simple as having a single equivalent node for each zone, or the next level of complexity, zonal equivalents with a single internal node where all zonal resources are connected. The effect of such a simplified model is that the same energy price applies to all resources in a given zone. The disadvantage of this model is that the outcome ignores the different locational effects that resources have in mitigating congestion. These effects are reflected in the Power Transfer Distribution Factors (PTDFs), that is the sensitivities of transmission flows to power injections (Wood and Wollenberg 1984). If the PTDFs are close for all resources in the same zone, this model is reasonably accurate. If, however, the PTDFs vary greatly within a zone, the resulting schedules are not optimal, and may not even be feasible. Experience gives credence to the claim that in systems with strong interconnections forming loops, a simplified network model is inefficient, and does not ensure feasible schedules. Further, it negatively affects reliability. For these reasons, all RTO markets in the United States have abandoned this market architecture. However, it remains the dominant model in Europe.

Zonal pricing (uniform price within a zone) does not necessarily require a simplified model. Zonal pricing can also be applied using a full network model. The zonal price is calculated as a weighted average price of all nodal prices within the zone. This price is efficient if the price dispersion within the zone is small, which, in turn, depends on the dispersion of PTDF within the zone. Again, in looped systems, price dispersion may be large, hence the zonal pricing is inefficient and leads to incorrect and skewed pricing signals.

Obviously, irrespective of the detail of the network model used in the forward markets, real-time dispatch requires a full network model. The necessity is dictated by operational considerations that require a feasible dispatch. Furthermore, efficient prices that correspond to an optimal dispatch are very important in real-time since they set incentives for proper behavior by market participants. This creates another serious problem for the zonal model, i.e., the inconsistent network models used by the forward and the real-time market. These inconsistencies can be extensively manipulated by the market participants to the detriment of the customers and the market as a whole, as clearly the energy crisis in California demonstrated. A comprehensive analysis of the problems associated with the zonal model is presented in Alaywan et al. (2004).

3.09.3.2 Zonal Energy Market Architecture Modeling

In the zonal model, the transmission network is divided in zones. Congestion between zones is managed through market mechanisms (interzonal congestion) and congestion within zones is managed like in the old environment, and the costs are spread to all customers within the zone. The assumption is that congestion within the zones is infrequent and it is sufficient to be priced on an average cost basis. This means that financial rights within the zones will be difficult to auction and to resell in a secondary market. Congestion between zones, on the other hand, is frequent and marginal cost pricing is deployed to promote its efficient use.

The objective of the interzonal congestion management optimization problem is to minimize the net cost of redispatch, as determined by the market participants' submitted incremental and decremental price bids. This objective function is equivalent to the net power generation cost objective used in conventional Optimal Power Flow (OPF) applications. The control variables in the interzonal congestion management optimization problem are the market participants' generator outputs in all congestion zones. For each generator, a set of generation quantities with associated adjustment incremental or decremental energy bids are submitted by the market participants for congestion management. Adjustable loads with demand-side bids can also be used as controls. Each market participant's adjustment incremental and decremental bids, and demand-side bids across zones, constitute an implicit bid for transmission.

The constraints in the interzonal congestion management optimization problem, besides limits on control variables, are the nodal active power flow balance equations and the interzonal interface active power flow inequality constraints. Intrazonal constraints are ignored. In some markets, for example the old California energy market, an additional set of constraints, not applicable in conventional OPFs, are added to the problem formulation to enforce market separation between market participants. These constraints enforce the condition that each market participant's net generation matches its net load. These constraints need to be formulated for all but one market participant, the latter being referred to as the 'reference market participant.' (The market separation and nodal power balance constraints will force the reference market participant's portfolio to be balanced at the solution without explicitly formulating a constraint for it.). The principle for enforcing these constraints is to ensure that the system operator does not intervene into the private markets of market participants.

A linear DC–OPF formulation is used, both for simplicity, and for reliable, robust marginal cost calculation. Power system losses are taken into account by dispatching effective power generation, which is the actual generation multiplied by the location-specific generator meter multiplier, which is derived by the location's penalty factor. A full network model, albeit lossless, is used for the system operator's control area. The interzonal congestion management optimization incorporates a linear power flow model. This model can be derived as the usual DC power flow formulation from the AC real power flow equations, by assuming negligible line resistances and small voltage angle differences, as presented in Section 3.15.2 Transmission Grid Modeling of the accompanying chapter 'Transmission Grid Fundamentals.' In this case, the active power balance equations in [17] of Section 3.15.2 can be written as the DC power flow equations as follows:

$$P = [B'] \times \theta \qquad [1]$$

The interzonal power flow constraints are linearized in a similar fashion. Linear power flow equations and constraints are also derived by linearizing the power flow equations and flow constraints about a point. The interzonal congestion management optimization problem is in Linear Programming (LP) formulation, as follows:

$$\min \sum_{l=1}^{L} \sum_{i=1}^{N} c_{l,i} \Delta P_{l,i} \qquad [2]$$

$$\begin{aligned}
&s.t.\ B'\Delta\theta = \Delta P \\
&F\theta \le Pf\max \\
&P_{l,i\min} \le P_{l,i} \le P_{l,i\max}\ \forall l = 1,2,\ldots,L; i = 1,2,\ldots,N \\
&\sum_{i=1}^{N} \Delta P_{l,i} = 0\ \forall l = 1,2,\ldots,L-1
\end{aligned}$$

where

l: Market participant index; i: node index; c: inc. bid;
θ: voltage phase vector,

$\Delta\theta$: change in voltage phase vector from preferred schedule,
P: nodal power injection vector
ΔP: change in nodal power injection vector from preferred
B': linearized Jacobian; F: branch power flow coefficient matrix
$Pf\text{max}$: branch power flow limit vector

At the optimal solution, the usage of congested transmission interfaces will be allocated to the market participants who most highly value the use of these interfaces. This is determined by the implicit value the market participants place on the interfaces through their adjustment incremental–decremental price bids, and the effectiveness of their resources in using the interfaces. The effectiveness of each resource depends on the particular location of the resource in the network. The market participants, which use the congested interfaces, pay for their usage of those interfaces. The schedules of market participants that are not allocating the usage of congested interzonal interfaces are adjusted so that they do not use the congested interfaces. In the case of insufficient resources or demand-side bids in a zone, some load may not be scheduled in the current forward market.

Market participants whose interzonal schedules are partially modified so that they still use some of a congested path are referred to as the 'marginal users' of congested interzonal interfaces, and they set the marginal price on that congested interface according to the implicit value they place on it through their adjustment incremental and decremental bids on each side of the congestion. Market participants with comparable effectiveness, but lower implicit value on an interface, are not allocated usage of the interface. Market participants for which the adjustment range is exhausted or do not supply bids become price takers on the congested paths.

The OPF solution provides all of the marginal cost information that the system operator needs in order to price usage of the congested interzonal interfaces. The system operator will charge each market participant for its usage of congested interzonal interfaces. Each market participant will see a uniform price for transporting power from one zone to another, irrespective of the particular location of its resources within congested zones.

3.09.3.3 Summary

Actual experience with the Zonal energy model in the United States has not been positive. The use of uplift payments to manage the congestion charges within zones can only work as long as the uplift charges remain small. However, as these 'socialized' charges for intrazonal congestion increase, all market participants must pay the charges, without regard to which transactions are contributing the most to the congestion. Since the socialization of the congestion costs creates no incentive to alleviate the congestion problem, the condition will not be alleviated through market mechanisms and it may worsen over time. In fact, averaging congestion charges across all market participants may actually create incentives to cause congestion in some areas, because users of the transmission grid will not see the true cost of their deliveries. Inevitably, the system operator will be required to intervene in order to maintain the security of grid operations. Actual experience has shown that the cost of this intervention can be very significant.

The fall back plan of creating additional zones to manage evolving congestion has also been very problematic. The new congested paths interact with existing long-term transmission rights on other paths, defining new transmission rights that respect existing contracts. In this situation, the zonal energy model becomes complex as the system operator must find a way to define new zone boundaries that solve the evolving congestion problem, in such a way, as to respect the existing transmission rights. As each new constrained boundary evolves, the congestion management problem becomes more complex, due to the interaction of new constraints on the existing physical zone boundaries. These complications create conditions that render the viability of the zonal energy model, its stated objectives of simplicity, and commercial efficiency questionable.

3.09.4 The Nodal Energy Market Architecture

3.09.4.1 Introduction

In this section, we present a brief description of the nodal energy market architecture.

The transition from a zonal to a nodal model in many jurisdictions has become a necessity, because of serious flaws of the zonal model. Actual experience strongly indicates that the zonal model creates inefficient incentives for locating new generation. Further, as we discussed in the previous section, several hidden complications of zonal pricing can be found from England to the old California model, with different ad hoc rules applied to create more and more complex structures to fight against the choices of market participants confronted with administrative prices. The real impact of zonal pricing is to create more administrative rules, poorer incentives for investment, demands to pay generators not to generate power, and proposals to 'socialize' the higher costs by using the taxing power of the system operator. Other problems include inefficient intrazonal congestion, infeasible forward market schedules, socialization of constraint mitigation cost, and lack of demand response.

As we mentioned earlier, the zonal model allows for substantial simplifications in the incorporation of the transmission grid in the market clearing. The rationale for these simplifications is that the differences between the commercial schedules and settlements, relative to the actual schedules required for maintaining reliability, could be resolved without significantly affecting the underlying incentives. The outcome of these design principles was that commercial schedules in the forward market are inconsistent with real-time requirements and operational constraints. In turn, this creates inefficient incentives for market participants and exacerbates any problems arising from the exercise of market power. The resulting incentives create the need for a system of rules and side payments that eliminate the presumed simplicity of the commercial model, both for short-run operations and long-term investment.

The nodal model aims to restore the consistency between the commercial model and the physical reality and between the forward and the real-time markets. The key elements of the nodal market include a bid-based, Security Constrained Unit Commitment (SCUC) for clearing forward markets with simultaneous optimization of energy and ancillary services, a Security Constrained Economic Dispatch (SCED) for clearing real-time markets, locational marginal prices, bilateral schedules, Financial Transmission Rights (FTRs) (see Section 3.09.5.3 Financial Transmission Rights Model), a consistent network model for commercial transactions recognizing actual physical conditions, and a multi-settlement system.

These market elements enhance reliability, better protect wholesale customers from volatility and gaming, incorporate price responsive demand in the markets, and encourage development of new resources, including Renewable Energy Resources (RESs).

3.09.4.2 Nodal Energy Market Architecture Modeling

The nodal market clearing problem includes next-day generation offers, demand bids, and bilateral transactions schedules. The objective of the problem is to minimize costs subject to all system resource and transmission constraints. Similar formulation is used to solve the real-time market problem. In all cases, the SCUC accepts data that define bids (i.e., generator constraints, generator costs, and costs for other resources) and the physical system (i.e., load forecast, reserve requirements, and the security constraints). The SCUC selects resources based on minimum cost, as reflected on bid prices and on physical deliverability by the transmission system.

The SCUC problem has long been viewed as a very complex and intractable optimization problem. One of the most popular methods for solving the SCUC problem has been the so-called Lagrangian Relaxation (LR) method. The accuracy of LR method was considered sufficient for industrial applications before the emergence of wholesale competitive energy markets. However, the development of competitive energy markets, where multiple generation owners compete to provide their products, has increased the pressure for more accurate unit commitment solutions. An alternative approach to LR based method that effectively addresses the new modeling requirements imposed by the system operator markets is based on Mixed Integer Programming (MIP) implementations. The classical MIP implementation utilizes cutting plane and branch and bound schemes. This method attempts to perform an implicit enumeration of all combinations of integer variables to locate the optimal solution. In theory, the MIP is the only method that can make this claim. It can, in fact, solve nonconvex problems with multiple local minima (Guan et al. 2003).

The framework of nodal model pricing was first proposed by Schweppe et al. (1988) and further developed by Hogan (1992). The nodal prices are typically calculated as dual variables or Lagrange multipliers from Optimal Power Flow (OPF) calculations performed to compute the optimal dispatch (Venkatesh et al. 1992). As far as characterization, in terms of auctions is concerned, nodal pricing may be viewed as inherently discriminatory, as different generators are paid different prices. In general terms, the optimal dispatch problem in this case can be set up as follows:

$$\min c(p) + c_N(p_N) \qquad [3]$$

subject to

$$H \cdot p \leq z^{\max} \qquad [4]$$

$$e^T \cdot p + p_N = 0 \qquad [5]$$

where p denotes a $(N-1) \times 1$ nodal power injection vector (excluding the reference bus) and H denotes the transfer admittance matrix (dimension $M \times (N-1)$) that relates the nodal power injections to branch power flows . e is a $(N-1) \times 1$ vector of all ones, $z^{\max}$ is the $M \times 1$ vector of power flow limits and c_i is the net cost–benefit function at bus i.

The Lagrangian for this optimization problem can be written as

$$L = \sum_i c_i(p_i) - \lambda\left(e^T \cdot p + p_N\right) - \mu^T\left(H \cdot p - z^{\max}\right) \qquad [6]$$

Differentiating the Lagrangian with respect to the power injections gives the nodal prices:

$$c'_N = \lambda = (\text{Nodal price at } N) \qquad [7]$$

$$c' = \lambda \cdot e + \mu^T H = (\text{Nodal prices at all other nodes}) \qquad [8]$$

Additional optimality conditions include the binding equalities from (4), the power balance constraint (8), and the complementarity conditions:

$$\mu_j \left(\sum_{k=1}^{N-1} h_{jk} p_k - z_k^{\max} \right) = 0 \forall j, \quad \mu_j \leq 0 \qquad [9]$$

Thus, in the absence of binding inequality constraints, all nodal prices are equal to λ. In the presence of binding constraints, the nodal price at the reference bus N is equal to λ, while the nodal prices at all other buses vary according to sensitivities of the network flow constraints (4) and the relative contribution of power injections at those buses to the congested lines.

3.09.4.3 Summary

All the energy markets in the United States have adopted the nodal energy market architecture paradigm. In this model, since the trading hubs and zones are based on mathematical aggregates rather than physical boundaries, there is not a requirement for the system operator to predict how current flow patterns on the transmission grid will change over time. As new areas of congestion develop with changing flow patterns, the aggregated nodal prices will reflect the changing system conditions, and market forces will decide how transmission reservations are valued over time. This market-based approach does not require the system operator to intervene in the marketplace by taking away old rights and defining new ones as conditions change. In effect, the market will decide which rights are valuable given the current system conditions.

As experience has shown, this design also supports efficient transmission grid operations. As conditions change, the market may define new trading hubs or zones, without the need to redefine existing ones. Since the congestion pricing reflects the actual congestion problems that are occurring on the transmission grid on a continuous basis, the market will find the most efficient solutions to congestion problems as they occur.

The result is reduced intervention in the market by the system operator and lower overall cost to manage the congestion problem. Furthermore, since with this design energy market outcomes reflect actual operating conditions, the nodal energy market offers substantial flexibility to market participants to create financial products that are separate from the physical market. If traders desire to trade only at the hubs or zones, they can do so at their discretion. They can acquire FTRs at the locations of their choosing (i.e., nodes, hubs, or zones) to develop FTR strategies to manage their exposure. Therefore, liquidity is not an issue, as the detractors of this market architecture usually claim (Ott 2003).

3.09.5 Transmission Rights Models

3.09.5.1 Introduction

The basic alternative types of transmission rights in the electricity market differ in the type of proposed property rights, how the rights are specified and measured, what type of financial instruments are involved, and other features, such as details about the design of primary and secondary markets.

Several types of property rights could be associated with transmission network access. A fundamental distinction is between financial and physical rights. Financial rights are rights to revenues associated with transmission congestion. They are conceived as purely financial instruments that have no direct effect on physical flows, but are used to hedge congestion costs associated with energy transactions or held for speculative purposes. In contrast, physical rights are rights to use transmission capacity. A physical right is a right to flow power over a transmission element or a set of transmission elements. In the case of physical rights, a mandatory release mechanism is always required, so that the holder of a physical right may not withhold that right from other users when it is not being used. There are some transmission rights that incorporate elements of both financial and physical rights.

In this section, we describe the most prevalent transmission right models: the Physical Transmission Rights (PTR) model and the Financial Transmission Rights (FTR) model. The FTR model could be based on a flow-gate model, or a point-to-point FTR model.

3.09.5.2 Physical Transmission Rights Model

A physical right is a right to flow power over a transmission element or a set of transmission elements. System operators hold yearly, monthly, and daily interconnection rights auctions to sell transmission capacity to market participants. Market participants may acquire interconnection rights either directly by participating in interconnection rights auctions or through interconnection right transfers. PTRs provide scheduling rights to market participants that are PTR holders.

PTRs allocated through yearly and monthly auctions or resulting from PTR transfers may be transferred by a transferor to a beneficiary. PTRs allocated through yearly auctions or resulting from PTR transfers may be totally or partially resold at the monthly and daily auctions. PTRs allocated through monthly auctions or resulting from PTR transfers may be totally or partially resold at daily auctions. These instruments are prevalent in the European energy markets.

3.09.5.3 Financial Transmission Rights Model

Financial rights are conceived as purely financial instruments that have no direct effect on physical flows, but are used to hedge congestion costs associated with energy transactions or held for speculative purposes (Treinen and Papalexopoulos 2002; 2005; Hogan 2002; Oren 1997). FTRs can be point-to-point or flow-gate rights, i.e., rights on specific paths. FTRs, also called Congestion Revenue Rights (CRRs) or Transmission Congestion Contracts (TCCs), have been implemented in all energy markets in the United States FTRs can be configured from node-to-node in the system or between aggregations of nodes, called hubs. Hubs are determined by the frequency and importance of commercial transactions, and they may be used instead of individual nodes to facilitate trading, and increase liquidity in the secondary markets. The energy price at a hub is usually determined as the load-weighted average price of all nodes comprising the hub.

A point-to-point transmission right can be further defined as either a forward (obligation) contract or an option contract. A forward financial contract from point A to point B in the network, pays its holder the energy price difference between B and A (price at B minus price at A), which can be negative at times. The forward contract is a perfect hedge if the holder schedules its right fully, since the contract payment or charge offsets completely the congestion charge or payment for using the transmission path. If the holder does not schedule the right, the contract may result in a payment, if the right is in the direction of congestion, or in a charge, if it is in the counter flow direction. In the first case, the payment is collected from other users of the transmission system, who in effect rent the right to use the transmission path from the holder. In the latter case, the charge represents the cost of the congestion that the holder causes by not scheduling the counter-flow energy, and it is used to pay holders of forward rights in the opposite direction.

An option contract gives the holder the right, but not the obligation, to exercise the contract; that is, the holder is only paid if there is congestion in the direction of the right, but never pays if congestion is in the opposite direction. Both flow-gate rights and point-to-point rights can be specified as either forwards or options.

Forwards and options require slightly different formulations for the auction of transmission rights. In the general case, the auction takes the form of an optimization model that selects transmission bids to maximize transmission revenue without exceeding the capacity of the transmission network. For forwards, the use of the transmission network is maximized by allowing counter flows. For options, the effect of counter flows is ignored by constraining the transactions to the physical capabilities of the network.

Flow-gate transmission rights are usually associated with proposals for decentralized (forward) wholesale electricity markets and the zonal energy model. On the other hand, point-to-point financial transmission rights (PTP FTRs) are usually associated with centralized, mandatory, or voluntary pools with a nodal architecture organization.

All FTRs outstanding at a given time must be simultaneously feasible. In other words, the transmission system under security constrained conditions must be able to accommodate all the potential energy flows represented by an outstanding set of FTRs. Simultaneous feasibility is initially determined in the distribution (auction or allocation) process and reconfirmed in subsequent distributions. The system operator ensures simultaneous feasibility by executing a Simultaneous Feasibility Test (SFT). Bids that are not simultaneously feasible are reduced in accordance with the FTR auction optimization formulation.

PTP FTRs have some desirable properties for the system as a whole, with the quantity of FTRs limited to the simultaneous capacity of the network. Two properties of such FTRs are particularly important:

- Revenue Adequacy: The congestion rentals accruing to the pool are adequate to make FTR payments, even when the dispatch and the flows on particular lines change assuming that all the FTRs awarded are simultaneously feasible (Hogan 1992).
- Commercial Protection: The FTRs can fully hedge against price changes between nodes for a fixed number of MW.

3.09.5.4 The Flow-Gate Model

A flow-gate may be defined as a physical transmission interface within the transmission system on which a limit is enforced by the system operator, because its operating condition is perceived to be critical to maintaining reliability and security of the power system as a whole. The interface could be a single element, such as a line or transformer or a set of elements. The limit is typically a specification of the maximum power flow allowed on the element and may be derived from thermal, stability, or other considerations. 'Commercially significant' flow-gates (CSFs) are determined from the set of the flow-gates in the system based on a threshold level of significance, typically the level of the congestion costs incurred in the flow-gates. Note that flow-gates are directional elements; that is the limits and rights on a given flow-gate are different in each direction, or they may be relevant in one direction only.

Sets of buses separated by commercially significant flow-gates and having similar shift factors or Power Transfer Distribution Factors (PTDFs) can be aggregated into zones. A key step in this exercise is the identification of CSFs. One approach is to designate every congested interface on the system as a CSF. Unfortunately, this can produce a very large number of CSFs and zones, resulting in increased complexity without a corresponding increase in the efficiency of the market. A more appropriate approach would seek to select CSFs in a manner that captures the majority of the system congestion, but not necessarily all of it. A suitable threshold (i.e., between 80 and 90%) may be selected. The measure of congestion in such a test should be the dollar value associated with the congestion, as opposed to the number of hours. This would imply that a constraint on a major interface for a few hours might be selected as a CSF before a constraint on a small interface congested for a larger number of hours.

There are two approaches that may be followed to perform such an exercise. The first is to use historical data, if available, and the second is to perform a simulation of the system for several years by deploying a Security Constrained Unit Commitment (SCUC) algorithm. In both approaches, the result will be a ranking by congestion costs of all transmission flow-gates, which can include lines, transformers, tie-lines, interfaces, and contingencies. Any contingency in the output of the model should be aggregated by the limiting element in order to determine the commercial value of the associated flow-gate.

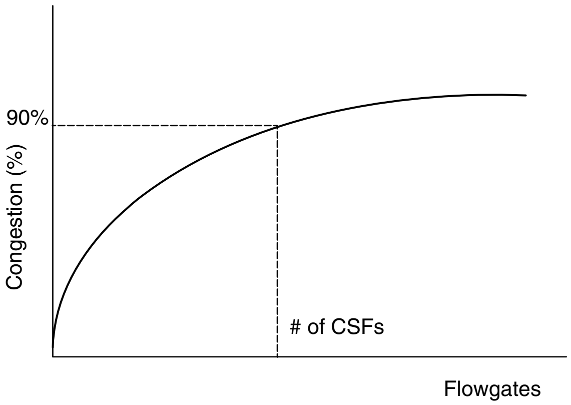

Figure 2 Commercially significant flow-gate identification.

The shadow prices for the binding constraints would yield a measure of the forecasted congestion costs. The congested interfaces would be ranked according to the congestion costs and a graph such as that shown in Figure 2 would be obtained. The graph depicts the congestion cost captured by a given number of flow-gates. Depending on the threshold selected, the designation of CSFs would be derived from the graph.

After the CSFs are determined, appropriate constraints on their directional power flow would augment the congestion management optimization problem. The solution to that problem, irrespective of the particular formulation and the level of detail employed in the network model, would yield marginal prices for the use of congested flow-gates. Market participants would then be charged or paid the marginal price for their scheduled use of congested flow-gates in the direction of congestion, or in the counter flow direction, respectively. The scheduled use of a given flow-gate by a market participant would be calculated by applying the relevant PTDF to that participant's supply and demand schedules. The congestion revenue collected from the flow-gate usage charges would be paid to the flow-gate right holders that acquire these rights in long-term flow-gate transmission capacity auctions. In this respect, the flow-gate rights provide a hedge against transmission congestion costs.

Proponents of the flow-gate model have argued that flow-gates and FTRs can provide a hedge against congestion charges however, since FTRs are subject to simultaneous feasibility and have limited liquidity (Chao and Peck 1996). Experience over the last 10 years, however, dispels this notion. In fact, the flow-gate model suffers from the same problems as the zonal energy model (see Section 3.09.4). Obviously, if congestion costs not accounted for by flow-gates increases, the market inefficiencies also increase. The serious issue of new congestion is also relevant in this debate. Similarly, since interface limits change almost continually, it is unclear what limits the system operator will deploy. Inevitably, these problems require serious interventions by the system operation and a very conservative approach leading to inefficient use of the transmission grid.

3.09.6 Energy Markets Trends

In this chapter, we present a brief exposition of energy market trends that are currently emerging and are expected to dominate the debate on energy markets in the future. This exposition will touch upon overarching challenges that are expected to affect the evolution, format, and configuration of the future energy market design in various jurisdictions.

The overall energy picture is vastly complicated today by the inescapable linkages between energy production and use and the environment. In particular, the risk of climate effects from emissions released by fossil fuel combustion will exert a profound influence on the world's energy options and choices over the decades ahead. It is widely accepted today that energy markets are not only vulnerable to the security of supply and price fluctuations, but also to weather and climate. Extreme weather events affect energy markets in various ways. For example, extended cold outbreaks or heat waves always lead in excessive electricity and/or fuel consumption, and therefore, to scarcity conditions and price spikes. Long-term climate variability may lead to population movements, and therefore, changes in energy consumption and the local energy markets. In addition, energy markets in arid and semiarid zones are more vulnerable to climate, because the variability is larger in these zones and sometimes is associated with the water budget. In this context, the old notion of energy security acquires new dimensions. Reliable access to the energy resources needed to support a healthy economy remains the core imperative, but in the twenty-first century energy security also means reducing the macroeconomic vulnerabilities inherent in the current geopolitical distribution of supply and demand and coming to grips with the environmental impacts of the current energy system.

A consensus is emerging for dealing with this very intractable problem by deploying a mandatory, economy-wide tradable permits system for limiting emissions of carbon dioxide and other greenhouse gases. At the same time, focus is placed for substantially improving energy efficiency and demand response throughout the economy (i.e., in buildings, equipment, industry, and transportation) and, at the same time, promoting energy supply options that advance a number of cross-cutting policy objectives, from reducing exposure to resource constraints and supply disruptions to reducing climate risks.

These policies should be designed to ensure adequate supplies of natural gas and to promote the expanded deployment of low-carbon energy alternatives–including advanced coal technologies with carbon sequestration, next-generation nuclear technology, and renewable sources for electricity production and transportation fuels. Further, these policies need to address siting of critical infrastructure, protect key energy facilities from terrorist attack, and improve the performance and reliability of the electricity system.

With respect to energy efficiency, it is important to focus on some myths related to this important resource. Clearly, no one doubts that increasing energy efficiency or reducing energy intensity (i.e., the energy needed to produce a given amount of GDP) is a key to economic growth. Without the relentless pursuit of energy efficiency, we would need much more energy to produce the same amount of wealth–and we would be producing a whole lot more emissions.

The obvious benefits of energy efficiency have led some people, however, to believe that energy efficiency can solve all our energy and climate problems. However, this is not true. First of all, there is the old Jevons Paradox, named after the nineteenth century British economist, Stanley Jevons, who pointed out that cheaper energy tends to lead to higher energy consumption, offsetting the gains of energy efficiency. This argument is generally accepted among economists. But there is another point to consider about energy efficiency, less well understood, which is that there are different types of energy efficiency measures that have different effects on carbon emissions. There are energy efficiency measures that do indeed reduce carbon emissions, but there are other measures that, unfortunately, have the opposite effect–they lead to higher carbon emissions.

A clear growth supply resource that has a major positive impact on the environment is renewable resources. Renewable energy already plays an important role in the energy supply of many countries today, primarily in the form of hydropower for electricity production and corn-based ethanol, as a transportation fuel. Other renewable options including wind, solar, and advanced biomass technologies for power generation, together with alternative transportation fuels from woody or fibrous (cellulosic) biomass and organic wastes, have made considerable progress in recent years, but still face substantial cost or technology hurdles, as well as, and in some cases, siting challenges. The massive penetration of renewables in certain regions is already distorting the energy markets, however, due to their intermittency and the subsidies they still enjoy, and their collective effect creates a very stressful market and system conditions. Current energy market design configurations need to be modified to be able to accommodate the massive penetration of renewables that is expected to change the energy mix in many regions worldwide.

Another major energy market development that is currently underway is the natural gas revolution. The natural gas market has recently been transformed by the rapid expansion of shale gas production. In 2008, the rise in oil prices was accompanied, and partly fueled, by a belief that an era of permanent scarcity was at hand. This mentality had deep roots extending back to the 1970s, when the United States went from being a minor importer of oil to a major importer. Falling oil output was considered simply inevitable. The only questions were at what rate petroleum imports would rise and whether that rate would be slowed. The outlook was much the same for natural gas. Production would inevitably decline. In the United States, the projection was that the country was on the way to spending \$100 billion a year to import liquefied natural gas from West Africa, the Middle East, and even Australia and Russia. The energy burden on the trade deficit would only increase, adding to the economic distress.

But that is not at all how things are turning out. Technology made the difference. A dozen years ago, shale gas amounted to only about 2% of US production. Today, it is 37% and rising. Natural gas is in such ample supply that its price has tanked.

This unanticipated abundance has ignited a new political argument about liquefied natural gas–not about how much the United States will import, but rather how much it should export. The oil story is also being rewritten. Net petroleum imports have fallen from 60% of total consumption in 2005 to 42% today. Part of the reason is on the demand side. The improving gasoline efficiency of cars will eventually reduce oil demand in the United States by at least a couple of million barrels per day.

The other part is the supply side–the turnaround in US oil production, which has risen 25% since 2008. It could increase by 600 000 barrels per day this year. The biggest part of the increase is coming from what has become the 'new thing' in energy–tight oil. That is the term for oil produced from tight rock formations, with the same technology used to produce shale gas. Tight oil is redrawing the map of North American oil. At the beginning of this year, North Dakota overtook California as the nation's third largest oil producing state. It did not stop there. It just overtook Alaska, to become number 2 after Texas. Tight oil could reach more than four million barrels per day by 2020. What really brings home the new reality is a milestone attained last year. In 2011, the United States registered the largest increase in oil production of any country outside of OPEC. If one takes a broader North American perspective, the changes in the supply picture are even more striking. The output of Canadian oil sands has tripled since 2000, and is now greater than Libya's output before its civil war began in February 2011. With oil demand in the United States declining, output rising and increasing integration with Canada, the United States is certainly on the way to becoming 'energy less dependent.'

As a result of these developments, coal power plants could replace natural gas power plants as the marginal generating units in clearing the auction-based energy market in many jurisdictions. Further, the dramatic increase in conventional generation production puts additional pressure on the renewable energy resources to achieve via technological improvements 'grid parity' and compete on merit in the marketplace without the subsidies and the preferential treatment that are currently in place in most jurisdictions.

Finally, a key factor, which has the potential to have a major impact on future energy trends is the consumer. After all, the consumer is supposed to be king in the free energy marketplace. Energy users are free to decide what kind of energy they will buy and from whom. Our energy markets are not only in a transition to a low-carbon energy supply, they are also still in a transition to free energy markets in most jurisdictions. What we may expect to happen is that although much is still being decided 'from the top,' consumers will more and more assert themselves. This will have far-reaching consequences for the structure of our energy markets.

For example, in Germany, Europe's biggest energy market, there is a battle going on between suppliers of 'green' and 'gray' energy, not only in political circles, but also among consumers. Nuclear power also got into the crossfire after Fukushima, when many German consumers decided to abandon suppliers with nuclear power in their portfolio. This skirmish was prematurely ended when the German government pulled the plug on nuclear power, but in other European countries the battle over nuclear power may well be decided in the end by the consumer rather than by those who think they know best concerning what type of energy is good for society.

3.09.7 Conclusion

In this chapter, we presented an overview of the energy markets including the role of the system operator and the advantages and disadvantages of the two basic market architectures currently in operation worldwide–the integrated and the unbundled market structures. We presented the bilateral market model, which is motivated by the concept that free market competition is the best way to achieve competition in an electricity market, and the pool market model which is motivated by the concern to accommodate the special characteristics of electric power networks within the electricity market trading process.

Finally, we focused on the presentation of the basic design of the most prevalent energy market models that are based on the integrated market architecture–the zonal and nodal energy market models. The key difference between the two is the granularity of the transmission representation in the energy market clearing. Specifically, in the zonal model only few key transmission constraints are represented in the clearing, while in the nodal model a detailed transmission model is present, giving rise to Locational Marginal Prices. The majority of the transmission constraints in the zonal model are not visible in the market clearing process. This means that congestion within zones (i.e., areas within which congestion management is performed outside the market) is socialized. The use of uplift payments to manage the congestion charges within zones can only work as long as the uplift charges remain small, which is not usually the case, at least in system with substantial transmission bottlenecks. As a result, the transition from a zonal to a nodal model in many jurisdictions has become a necessity, because of the serious flaws of the zonal model.

We also presented the basic design of various transmission rights markets that are required to provide hedging to energy market participants–the physical transmission right model, the financial transmission rights model, and the flow-gates model. The most successful architecture is the financial transmission model, which is the predominant model in the United States.

Finally, we presented a brief exposition of energy market trends that are currently emerging and are expected to dominate the debate on energy markets in the future. This exposition touched upon overarching challenges that are expected to affect the evolution, format, and configuration of the future energy market design in various jurisdictions.

Glossary

Distribution network The medium or low voltage networks used to distribute electricity at lower distances from the suburbs to the end-users; usually on wooden poles.

Interruption No provision of electricity or natural gas to end-users.

Outage Nonoperation of an element due to either breakdown or maintenance.

Pipeline Construction that carries significant amount of natural gas. The diameter changes with the capacity.

Substation Facility changing the level of voltage to lower or higher levels in AC networks.

Transformer Device which changes the amplitude of voltage in alternating currents (AC).

Transmission network The high voltage (above 30 kV) network used to transfer significant quantities of electricity from generators to the suburbs of a city; usually on steel towers.

3.10.1 Introduction

Energy networks are an indisputable part of the energy infrastructure making energy services accessible to increasing parts of global population. Natural gas or oil pipelines aim at delivering fuels to end-users, whereas electricity interconnectors and lines deliver electricity from production sources to consumption nodes. All energy services depend on the efficient functionality of respective energy networks, thus the latter's vulnerability to external factors is of great importance to the consumer's utility.

http://dx.doi.org/10.1016/B978-0-12-384703-4.00319-1

In particular, electricity networks (i.e., transmission and distribution (T&D)) are the backbone of power systems. Their mission is to transfer the electricity produced to final customers, safely and reliably, at high power quality and as efficiently as possible. The cost of electricity networks represents a high share of total energy infrastructure costs and is susceptible to rising prices of copper and aluminum, the main materials used for T&D networks. The existing power system infrastructure in the United States is valued at $\$800 \times 10^9$ (Kuzenovic et al. 2008), whereas according to estimations of the Public Power Corporation of Greece (PPC), 35% of the cost of electricity production facilities comes from the cost of networks. Additionally, building and maintaining this infrastructure requires well-trained personnel and significant time and machinery. Problems occurring in these networks lead to outages, sometimes felt as interruptions to the customers.

The impact of a major power outage will be determined by the nature of the affected area, the duration of the disturbance, the time of day, the weather conditions, etc. A major blackout will affect all functions in a society, and economical activity stops in a region without electricity (US–Canada Task Force 2004). People in large cities will usually be more affected than those living in rural areas. Indirect effects of a blackout can have a major spread in time and space, for example, an increase in crimes in larger cities, interruptions in communications and transportations, and low indoor temperatures during wintertime. Especially critical is the state of dependence between telecommunications and power systems. After a few days there can be a shortage of food and fuel, which affects the reserve supply of electricity from backup generators.

Therefore, it is necessary to understand to what extent the energy networks are vulnerable to climate, how much their operations are affected, and how we can decrease vulnerability based on the experience of utilities around the world. The structure of this section is as follows.

First, a small summary of how electricity networks and fuel pipelines are structured is provided for the reader unfamiliar with these infrastructures. Then, how extreme weather effects and changes in the sea level affect the T&D networks will be analyzed. At the end of that section a summary table of the level of vulnerability and the associated costs will be provided for each one of these weather effects. The next section refers to how the T&D networks could potentially help in mitigating climate effects, and emphasis is given on the recent advances reducing losses on these networks and the potential impact of Distributed Generation (DG). Finally, suggestions for the operators and developers of T&D networks and fuel pipelines are made.

3.10.2 Introduction to Electricity Networks and Fuel Pipelines Infrastructure

In this section, a short introduction to the structure of electrical networks is made. The necessary clarification between transmission and distribution networks is made and some general outlines of their construction and operation is given. This is essential so that the reader can have an adequate grasp of the notion of electrical grids and understand their potential vulnerabilities to external impacts. Also some details on fuel pipelines will be provided.

3.10.2.1 Construction Details

3.10.2.1.1 Transmission Systems

Transmission systems consist, in the vast majority (estimated at 95%) of the lines built, of overhead lines using tall steel towers with different configurations, depending on the voltage level, the transmission capacity, and any special precautions due to, for example, crossing a river or passing through a mountainous area. There may be a single circuit or double circuits at one tower, depending on its design.

The higher the transmission line voltage, the higher the steel tower and the wider the area required. For instance, a typical single 150 kV transmission tower has a width of 13.6 m, whereas a single circuit 400-kV overhead line has a width of 20.6 m. The distance between successive towers ranges between 150 and 500 m depending on the ground morphology and any potential obstacles, whereas distances larger than 1 km have been recorded (see bibliography). Typical transmission lines are shown in Figure 1.

The vast majority of transmission lines operate at AC, but transmission at DC level has started becoming popular for long distances and interconnections with submarine cables like the interconnection of British and Dutch transmission networks, NationalGrid, and TenneT (BritNed Go Live video 2012).

3.10.2.1.2 Distribution Networks

Distribution lines are further divided into medium voltage (MV) and low voltage (LV) levels. Distribution networks are extremely extended, with thousands of kilometers around the world to reach the final customers. In Europe, the European Network of Transmission System Operators (ENTSO-E) controls 200 000 km of HV lines (ENTSO-E 2012), which is the same as the length of distribution lines solely in Greece. The overhead lines of this type usually consist of wooden or sometimes concrete poles. Figure 2 shows a typical transformer of MV/LV, 20 kV/400 V in a crossroad in the suburbs of Iraklion, Crete. On top of the poles are the MV lines, and the 5 lines below are the LV lines (three phases, one neutral and one phase also feeding the street lighting).

3.10.2.1.3 Network Topologies

Transmission networks, due to their significance for meeting demand, are usually constructed in loop or meshed architecture. In this way if one line for some reason is unavailable, either due to failure or due to maintenance, the flow to the rest of the network will remain. This is the N-1 criterion. In some cases, an N-2 or even N-3 criterion applies. Radial transmission lines are usually used for meeting the demand of relatively few and remote customers.

Distribution systems sometimes are meshed as the transmission systems, mainly for MV main feeders. For most low voltage networks, especially in rural areas, they are radial. This means that if a part breaks down, the related customers remain without electricity.

Both radial and meshed networks are shown in Figure 3.

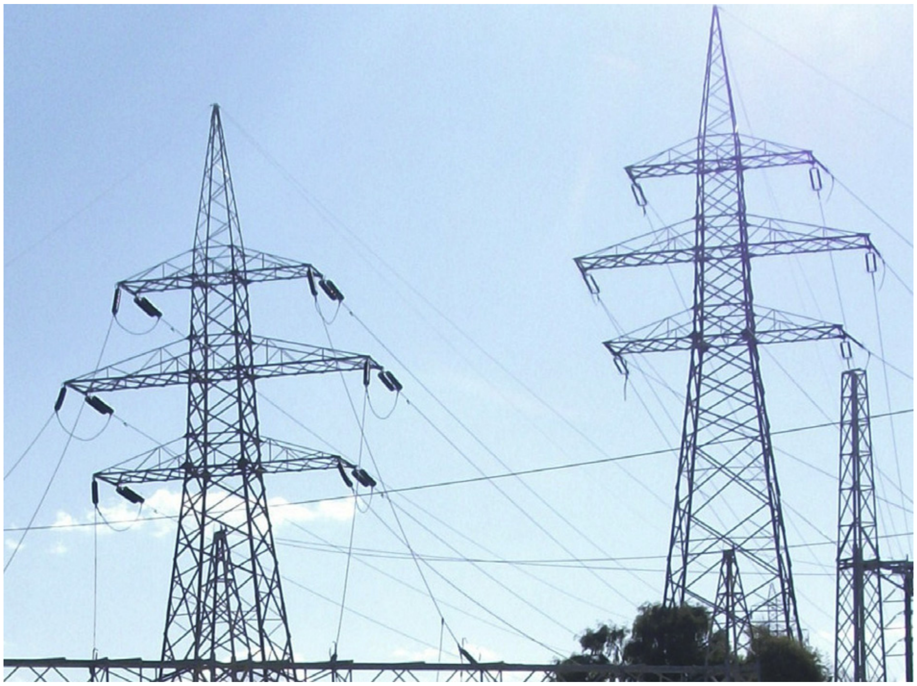

Figure 1 Typical high voltage towers (150 kV).

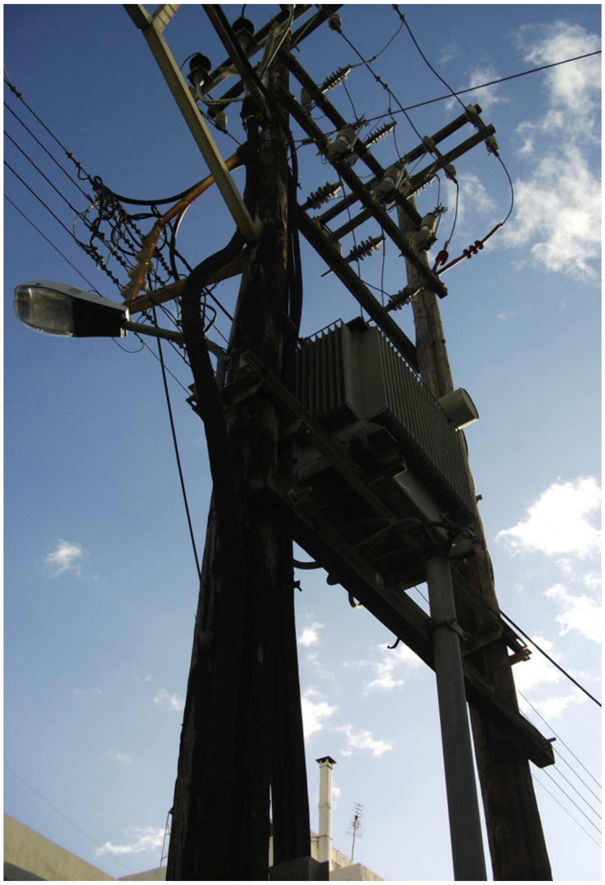

Figure 2 Typical MV/LV transformer and distribution level construction.

Table 1 describes the typical voltage ratings for electricity grids used by utilities around the world. Ratings above 230 kV are considered as extra high voltage. More details and maps of transmission systems can be found at the web sites of transmission system operators (TSOs) and the ENTSO-E.

3.10.2.2 Causes of Outages in Electrical Grids

An attempt is made here to distinguish the concepts of outages and interruptions in order to facilitate the reader's comprehension of the causes of outages in electrical grids. Outage is the breakdown or scheduled maintenance of a network component, meaning that this component is temporarily out of service. 'Interruption' means cessation of service to customers. Outages may cause interruptions but this not always the case. Very often outages take place but are not noticed by the customers at all. Additionally, the duration of an outage is usually longer than the interruption time because, using different network routes or even backup generators, some or all customers served by the faulty equipment can be served after some time.

Weather is one of the most important causes for outages. In normal weather, grid faults are occasional; under adverse weather, outages occur more often. The lower the voltage, the more frequent such events may be, but much fewer customers are affected.

Under extreme weather conditions, however, the outages occur increasingly often and may be caused by severe damage to the equipment itself. For instance, based on the Hellenic Transmission System Operator (HTSO) reports for 2011 (HTSO-Web-site 2012), at least 1100 MWh were not served due to adverse weather conditions and outage at the

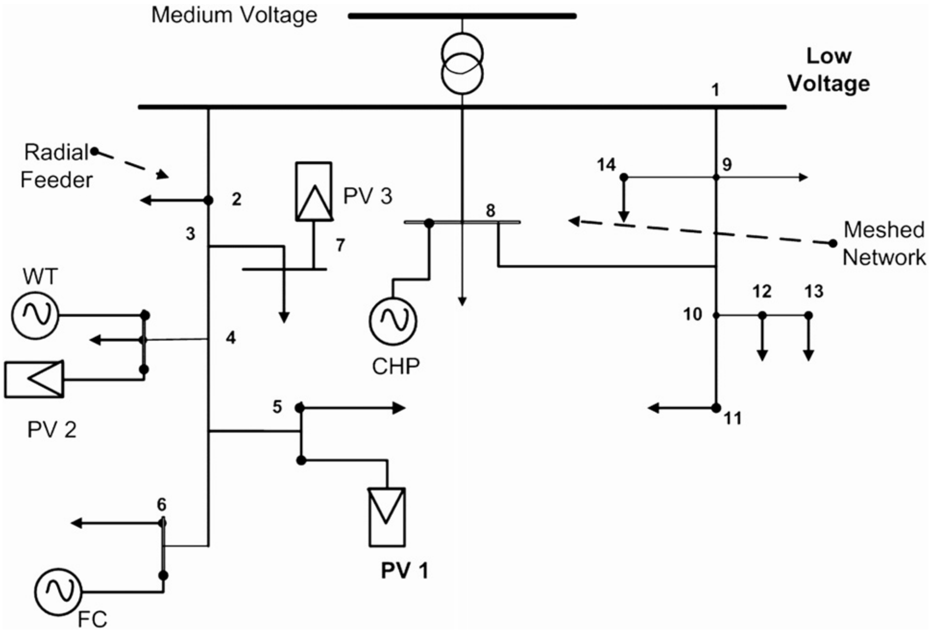

Figure 3 Typical distribution network with radial and meshed feeders and DG sources connected.

Table 1 Indicative line-to-line voltage level for distribution and transmission grids

Transmission level	*Medium voltage distribution level*	*Low voltage distribution level*
66 kV, 132 kV, 150 kV	6.6 kV, 11 kV, 15 kV	110 V, 220 V, 400 V
220 kV, 380 kV (Swiss)-400 kV, 500 kV, 750 kV (extra high voltage)	20 kV, 21 kV, 33 kV	Generally below 1 kV

transmission level. These reports do not mention related faults at the distribution level.

With respect to extreme weather events, snowstorms are regarded as events with both the highest duration and amount of energy not served, whereas lightning and extreme wind conditions are also frequent causes of outages and interruptions. Other events related to climate variability such as sea level rise, increased precipitation, drought, and rise of temperature could also affect the operation of electricity networks either in the short or longer term. Considerations of climate impacts would even require a reconfiguration of the existing electricity grid, namely the inclusion of adaptation measures in the planning procedure.

3.10.2.3 Oil and Natural Gas Pipelines

Because of technical and security reasons, pipelines are usually underground with checkpoints at the ground level. At various points along the pipeline, including at line junctions, compressor stations pressurize the natural gas to ensure a continuous and regulated flow. Transport lines vary in size, generally ranging from 24 to 36 inches in diameter, and have right-of-way widths of up to 200 feet, depending on the size and number of lines. One final point near seaside may be a terminal station either for compressing or storing liquified natural gas (LNG).

Oil pipelines may either end at a terminal station or at a refinery. The pipelines are very often constructed with polyethylene HDPE or with metals. Being underground, they are not as exposed to extreme weather conditions as electricity networks are, except in cases of coastal location affected by sea level rise. The main fault that may take place is their destruction, break at one point, or corrosion. The main issues that may exist are the ones of increased consumption and destruction of the soil. Where available, some information will be provided in addition to that given for electricity networks.

3.10.3 Vulnerability to Climate Variability Phenomena

3.10.3.1 Cold/Ice Storms

Transmission lines have been designed to account for increased levels of snow cover on them. Similar but not so strict precautions have been taken for distribution networks as well. Unusual snow cover, however, especially in high-temperature areas where the tension of the line gets lower, may create falls of conductors more often due to the weight of snow or ice. This may get even worse when the temperature drops to around 0 °C together with high precipitation and wind, which very often leads to wet snow accumulation reaching even 20 cm on overhead power lines. Experience from such events with impressive but discouraging examples can be found in cold climate countries like Iceland (Elíasson 2005). Experts on transmission systems consider this phenomenon to be the main icing problem.

Combination of wind and ice cover is the most threatening scenario for overhead lines. The surface of the line exposed to wind is wider as the snow becomes ice. Therefore, in addition to ice weight, mechanical stress caused by wind increases because of the cross section of the line, as can be seen in the simplified diagram in Figure 4. This precaution has to be taken into account when calculating the mechanical characteristics of the line and the span between successive towers.

Wind combined with snow can create even more problems by carrying precipitation with high salinity, sand particles, or other pollutant material to the insulators. Under these circumstances, insulators may suffer from flashover.

Climate variability impacts include extreme snow cover and frequent events of extremely low temperatures even in areas not so familiar with such weather phenomena, thereby causing severe consequences due to less experienced personnel.

To make matters worse, under such weather conditions access to the faulty equipment becomes particularly difficult, hence prolonging the interruption. The longest duration of outage caused by weather in Greece in 2011 was 9.5 days due to fallen transmission towers in the windy area of South Evia near Athens during increased snowfall. This area is shown in Figure 5.

In January 1998, Eastern Canada was hit by the worst ice storm in modern time. 1.6 million users were left without electricity and a large share of the 5.5 million inhabitants of the region suffered from power outages. In some areas, the restorations took nearly 4 weeks, and residual repairs of the power grid continued into early summer (Fischer and Molin 2001). A similar event in Germany in 2005 led to collapse of 70 transmission towers, leaving 200 000 people without electricity (Fikke et al. 2007).

3.10.3.2 Lightning

Lightning is a severe event mostly for transmission and distribution equipment. According to a recent Metoffice presentation (McColl et al. 2011), lightning is the primary cause of outages in transmission lines and the second most frequent cause for distribution lines. Lightning is found to cause damages to distribution lines in urban areas very rarely, contrary to rural areas.

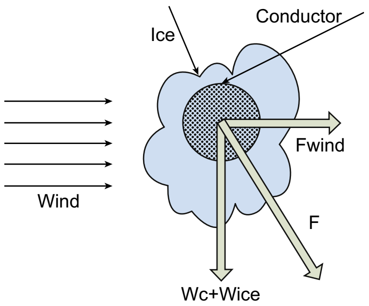

Figure 4 Simplified diagram of forces on a conductor with ice under windy conditions.

One important example of a blackout attributed to lightning took place in Brazil on March 1999 when 97 million customers were affected by a cascading transmission fault initially caused by lightning strike, which cut electricity for about 5 h. Another characteristic event of repeated lightning strikes is the one recorded in 18 January 2010 on the island of Crete (Thalassinakis and Papazoglou 2010). During this incident, nine lightning strikes were detected within a few kilometers of the largest city of the island, Iraklion, near the power station and the dispatching center. Within 19 min and under heavy rainfall, a brownout of the power system of the island was created. This was mainly due to protection coordination, the experience of personnel at the dispatching center, and the high spinning reserve that helped in avoiding a total blackout of the autonomous power system of Crete. Even though the electricity cut lasted for few hours, critical equipments, such as generators, were efficiently protected and allowed the power system to recover quickly from this disturbance. A list of other blackouts triggered by thunderstorms can be found in Chapter 6 of Knight (2001).

Overall, the electrical equipment manufacturers, in cooperation with utilities, have developed protection schemes in order to mitigate effects of lightning to equipment and human life. Also they have made significant progress in equipment used to protect final customers from breakdowns in their equipment due to lightning strokes.

Regarding pipelines, direct strike of lightning is not as intimidating as for electricity lines because pipelines are not the highest objects in their area. What may be threatening is the side effect of lightning on electricity network infrastructure due to voltage rise on the ground proximate to the lightning strike. In such a condition, breakdown of polyethylene may occur, depending on the circumstances. The result of this incident may be a hole in the pipeline resulting in gas leakage, the severity of which depends on the current discharge of the lightning strike, and the dielectric constant of both the pipeline material and the special resistance the soil presents (Caulker et al. 2008).

Thunderstorms are likely to be more intense and/or frequent (IPCC 2007); thus efforts for protecting equipment against this event should be intensified during the adaptation process. Furthermore, efficient coordination of protection devices and sufficiently trained personnel is required to alleviate the impacts after a lightning stroke. If these considerations are not taken into account, some transmission or distribution equipment may be destroyed and electricity cuts may last longer.

3.10.3.3 Wind

Climate effects include frequent extreme wind speeds, and a possible increase in the probability of local hurricanes. Wind is a severe threat for both transmission and distribution network overhead lines by affecting their operation in one of the following ways:

- Dismantling of one or more of the conductors due to their vibration.

This may happen if wind has the power to take away one of the conductors of an overhead line. Usually, precautions, such as dampers loops (bretelle), have been taken in order to mitigate this effect.

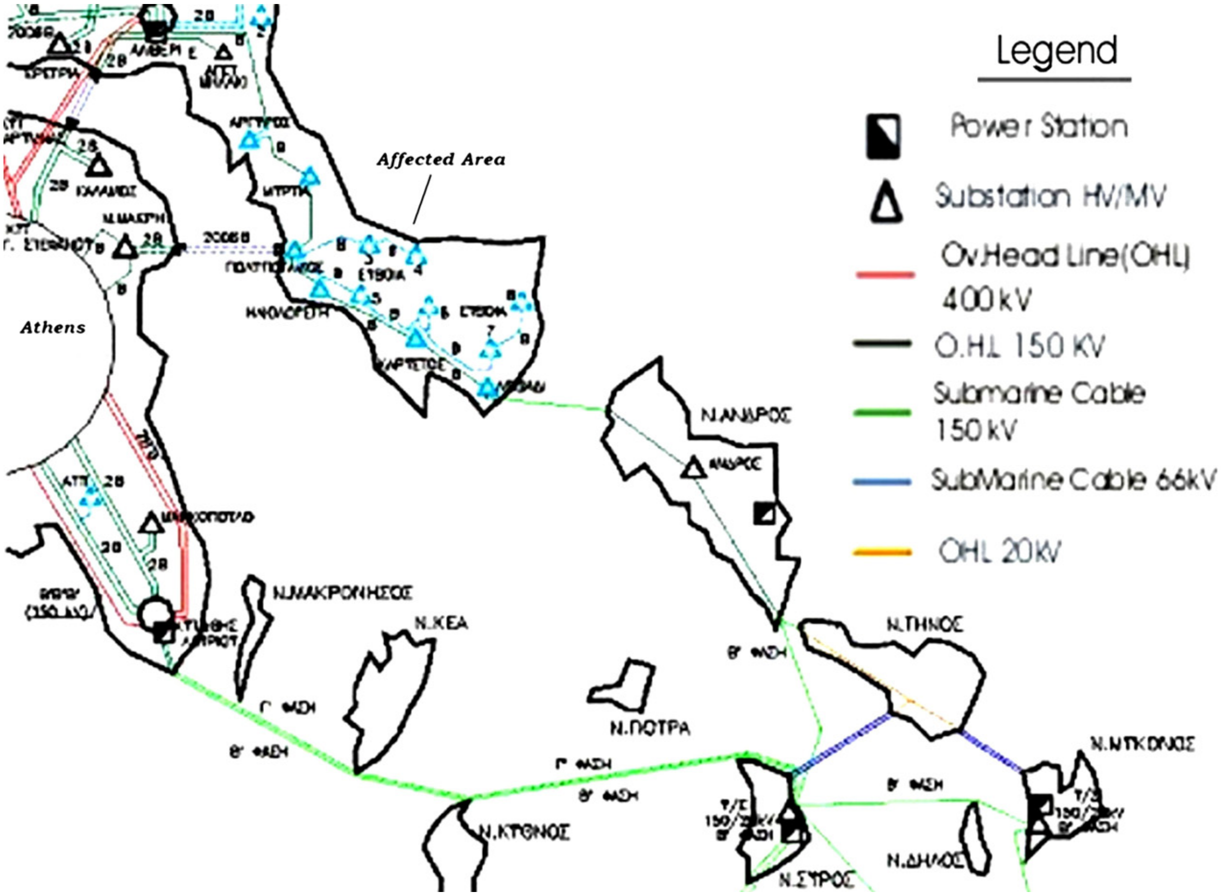

Figure 5 Map of the affected area. This map shows the scheduled interconnections of the Cyclades islands to the mainland (Hatziargyriou Vrontisi et al. 2007).

- Trees falling on transmission and distribution lines.

This is a frequent event especially with regard to distribution lines running across forests or suburban areas. It is estimated that 50% of the faults taking place at the distribution system level are caused by falling trees. During ‘Lothar’ and ‘Martin’ storms in France in December 1999 (Ward 2010), 90% of the faults in the distribution networks were caused by falling trees causing disconnection of 415 million kWh mainly due to distribution system disturbance.

- Under high wind speed circumstances parts of trees may fall on distribution lines.

The simplest disturbance caused by this event may be that a line grounds to short circuit. Usually, this is cleared by the protection devices of the distribution networks, leaving customers without electricity. However, by taking away the tree or branch the disturbance is resolved. A more severe impact of high wind speeds may be a three-phase fault when a branch or a tree remains on the three conductors of the overhead line. Even at these milder situations, a collapse of trees on distribution lines causing the poles to collapse is likely but with relatively limited consequences. Such an event will require more personnel hours in order to fix the damage than simple electrical faults. The duration of electricity cuts will increase significantly as similar events occur more often.

- Objects on the lines.

Increased wind speed may cause some objects to ‘fly’ over some distances and finally land on the transmission lines. This happens at least once per year at the transmission system of Crete, with nylons used in greenhouses found landed on a section of a transmission line. Increased frequency of high wind speeds will result in an increased frequency of such incidents.

Wind combined with low temperatures and rain may create wet snow effect, thoroughly described in the cold/ice subsection.

3.10.3.4 Rise of Temperature and Electricity Networks

Generally, the capability of electricity networks to transfer electricity is decreased when the temperature increases. At the same time Ohmic losses are increased as can be seen in the following formula:

$$R_2 = R_1 \frac{T + t_2}{T + t_1}$$

where R_2 and R_1 are the conductor resistances at t_2 and t_1 °C (Saadat 2004).

The overload capacity, the efficiency, and the lifetime of the transformers are reduced under high temperatures. Extreme temperatures adversely affect the insulating properties of the transformer. Problems have occurred with transformers designed to cool off at night being unable to cool down sufficiently during warm nights and therefore begin the next day with higher starting temperatures. This is the major cause of most transformer failures (Georgilakis 2009). An additional issue raised by the British Columbia Hydro is the association of temperature increase with beetle infestation (Cigre Tutorial 2011). BC Hydro express their concern as regards the correlation of vegetation and network infrastructure by providing a specialized section on their website dealing with this issue (BC Hydro 2012).

With regard to underground cables, the expected increase in soil temperature may not be as high as in air temperature; however, temperature drain is an essential parameter for the loading of the line. Therefore, the capacity of the electricity grid to transfer power to the customers is reduced as the temperature rises and hence the capacity of the same transmission or distribution line will be lower than under normal conditions.

Heatwaves are expected to become more frequent (IPCC 2007) and as a result the extreme temperatures during summer periods will decrease the capacity of electricity networks. This will pose difficulties in meeting the summer peak demand that is found in most southern European countries, as in the case of southern Greece in July 2004 (Vournas et al. 2005). As a consequence, during heatwave periods the interruptions due to a decrease in both generation and network capacity are expected to become more frequent, unless costly investments in electricity infrastructure take place along with energy efficiency measures on the demand side of power systems.

3.10.3.5 Drought

Droughts do not pose a direct risk for operation of electricity networks as do other climate disturbances examined above. However, specific cases when droughts create complications to the functionality of electricity networks have been detected. The most severe impact of droughts is the increased risk of fire and thus the possible destruction of wooden poles or transmission lines. If such an event takes place, both the restoration time and the resources (capital and human) required for restoration are significant.

Another issue to be considered in cases of drought combined with moisture and salinity is insulator flashover. Salinity and dust due to drought remain on the insulators and when combined with moisture, favorable conditions for insulator flashover can be formed that may lead to their destruction and the consequent faults on the transmission lines. Utilities using helicopters for transmission networks or water carrier trucks wash the insulators at both the transmission and distribution networks during the summer time. To combat this problem, new silicon-coated insulating materials have been developed (Siderakis et al. 2008).

Drought can limit the moisture on the ground, increasing local temperature and thus reducing the capacity of underground cables. Decrease in moisture of the soil decreases electrical conductivity of the soil, increasing the grounding resistance of the substation or other equipment grounding system. This may affect the ability of the faulty part of the transmission or distribution network to 'clear' the fault (caused, e.g., by lightning or short-circuit).

Generation facilities, in particular hydroelectric and thermal ones, are far more vulnerable than electricity grids to drought as has been examined in previous sections. Thus, a change in electricity flow can be seen, resulting in increased loading or even overloading of specific lines. Thus, this vulnerability of power generation combined with non–weather-related events in the transmission systems could create blackouts that otherwise could have been avoided. More details on this issue can be found in the generation facilities-related chapter and in reports for Western Utilities (DOE 2009) and especially Texas (Webber 2012). Drought concern in Texas is rather high as the Electric Reliability Council of Texas (ERCOT) has recently organized a drought best practices workshop (ERCOT 2012).

3.10.3.6 Floods

Floods do not constitute any significant threats to electricity networks owing to the height of the transmission and distribution lines. However, distribution networks with lower height from the ground are more exposed to such a threat. The most severe threat for overhead lines comes from the wet soil of foundation factor that, especially under windy circumstances, might lead to collapse of some wooden poles.

High voltage/medium voltage substations are more vulnerable to floods because they are mostly installed outdoors. Part of the installation may get flooded much easier than an overhead line. In such a case, the substation goes out of order, leaving hundreds of customers without electricity. The repair of the installation would require the drainage of the water away from the facility and possibly the substitution of significant part of the equipment, which are capital- and human resources-intensive procedures. Low lying areas are more vulnerable to this event. One significant outage was recorded in the Philippines in 2009 during the typhoon Ondoy, which flooded three 230-kV substations including the one feeding the Luzon Metro system (NGCP 2011).

Less severe due to fewer customers affected, but more probable, is the flooding of MV/LV underground or ground floor substations that can be found especially in urban areas. Building such substations is not an uncommon practice in most cities of the world due to lack of space and esthetic reasons. Generally, utilities have taken precautions during the construction of substations in order to ensure water drainage, but improved drainage and antiflood measures of new substations are regarded as possible adaptation measures.

Overall, future energy projects located in flood prone areas will face increased capital costs due to both legislative and insurance pressures.

3.10.3.7 Rise of Sea Level

An important consideration for adapting to sea-level rise is the location of energy infrastructure, namely power plants, substations, and networks. Especially because this impact would only appear at a significant magnitude in the long term, it is expected that utilities and network operators will plan new investments accordingly.

The water level rise is not expected to create more severe problems than the floods; thus vulnerability of transmission and distribution lines can be considered almost negligible. During the forthcoming years, however, significant numbers of undersea cables are going to be laid to interconnect insular areas or large power systems in Europe and North Africa (Desertec 2012). Therefore, this should be taken into account before laying these cables. The precautions that should be taken mainly involve the relocation of infrastructure at a higher altitude. Additionally, natural gas infrastructure and in particular LNG terminals – commonly located on coasts – may also require relocation; pipelines near the shore may have to be transferred to higher elevations as well as terminal stations for tankers.

3.10.3.8 Landslide

Landslides are expected to occur more frequently as a result of increased rainfall or rapidly melting snow. Such an incident may threaten distribution networks that are erected on wooden poles and are generally weaker than steel constructions of transmission lines and hence much easier to collapse. These events may not occur as frequently as disturbances due to ice, wind, or lightning, but the restoration time once a part of the electricity network is damaged is much longer. Such an example comes from Taiwan in 1999 when one transmission tower collapsed, leading to 8.5 million customers disconnected (Lee and Hsieh 2001).

Landslides can also affect natural gas pipelines, like the rockslide transformed into a debris flow severing a natural gas pipeline in Western British Columbia in June 2002 (Boultbee et al. 2006). Another important issue related to increase of average temperature is the melting of permafrost in Arctic regions and the consequent impacts on infrastructure and especially fossil fuel pipelines that may result from the melting. Russian scientists have expressed their related fears during a workshop in Iceland (Cigre Tutorial 2011).

3.10.3.9 Discussion of Vulnerability of Networks to Climate Variability

Overall, from the analysis above regarding the vulnerability of energy networks to weather effects, it can be concluded that extreme climate variability may lead to the malfunction of electricity and other energy networks. In terms of frequency and intensity of impacts, ice storms are considered to pose the greatest risk to electricity networks, especially when combined with wind, whereas other impacts such as floods, landslides, and sea level rise are considered milder.

Compared to electricity networks, pipelines, usually being underground, are more vulnerable to any parameter affecting the ground like floods and landslides and are rather vulnerable to sea level increase when LNG tanks are considered. Table 2 summarizes the frequency, restoration time, and cost of restoration for the above-mentioned effects, using descriptive variables as stated in Table 3.

Ranking the weather effects, taking into account their frequency to occur as described in Table 2, the restoration time, the number of affected customers, and the restoration cost, we can derive a vulnerability matrix as described in Table 4. This comes from assigning values 1 for low frequency or small impact and 3 for high frequency or high impact and multiplying these three values. The maximum vulnerability is 27 points. Clearly, electricity networks are more vulnerable to cold\ice storms and wind.

3.10.4 The Role of Electricity Networks in Mitigating Human Impact on Climate Variability

Planning of electricity networks is considered as an important measure to react to climate effects. The most important contribution to climate mitigation is the increase in the efficiency of transmission and distribution to final customers, leading to decrease in energy losses and thus enhancement of

Table 2 Weather events and their impact on networks

Weather event	*Frequency of problems caused*	*Restoration time*	*Cost of restoration*
Cold/ice storms	Medium–high	Medium–high	Medium-high
Lightning	High	Small–medium	Small-medium
Wind	High	Small–medium	Medium
Floods	Low	High	Medium to high
Temperature rise	Medium	Medium	Small to medium
Drought	Low–medium	Short–medium term	Medium
Rise of sea level	Very low–low	High	High
Landslides	Low	High	Medium

Table 3 Explaining ‘fuzzy’ variables

Characterization	*Frequency of problems caused*	*Restoration time*	*Cost of restoration*
Low	Rather rare events	Less than one day	Limited equipment needs replacement
Medium	May happen once per year	Less than a week	Replacement of some equipment, e.g., few poles a couple of tower
High	Quite possible when such conditions have been predicted	More than a week	Significant capital required

Table 4 Vulnerability

Weather event	*Electricity networks vulnerability index*
Cold/Ice storrns	15
Lightning	7
Wind	11
Floods	7
Temperature rise	6
Drought	5
Rise of sea level	4
Landslides	6

energy savings. This can be achieved either by utilizing more efficient equipment or by more efficient management of the existing equipment. The latter can be a way of improving access to 'cleaner' energy resources existing in remote or even harsh weather areas. This paragraph will provide some main measures that aim at the improvement of network efficiency.

3.10.4.1 Improvement of Equipment Aiming at Loss Reduction

3.10.4.1.1 Advances in Transmission Lines

One significant advance in cabling technologies is the development of high-temperature low-sag (HTLS) transmission lines. This technology reduces the sag of the cable, making contact with trees less likely to occur. Additionally, the technology presents lower resistance than the existing overhead lines and higher current rating, both of which result in fewer losses. Moreover, they can replace conventional conductors with no (or minimal) modifications to structures. The most important benefit of this technology is that it can significantly increase the rating of a transmission line with no (or minimal) licensing requirements or public opposition and in a very short period of time.

Examples of major installations in North America that use cables with this type of technology can be found in Clairmont (2008). In the same document, the measurements taken and some installation photos are also provided. Regarding Europe, a comparative study on these technologies from Ireland (Kavanagh and Armstrong 2010) indicated the Gap technology as most suitable. Compared with the current installation of ACSR cable with 943 A for 430 mm^2, the Gap conductor has a thermal limit of 1409 A. On the island of Crete, the ACSS conductor type is used to replace ASCR lines using the same towers in the Ierapetra–Sitia 150-kV transmission line.

3.10.4.1.2 Improved Transformers

Transformers help in changing voltage amplitude from generation level to transmission/distribution level and finally to the final customer. A simple system of the required transformers of a relatively small power system necessary to transfer electricity from production point to consumption is shown in Figure 6. The voltage ratings are typical values of networks in Greece. One can easily see that there are at least three transformers on our way to the customer. Each one of these transformers presents a variety of losses (Olivares-Galvan et al. 2009). Most important are iron losses constant with the load and copper or load losses changing with the loading of the transformer. When the load is doubled, these losses are increased four times. One typical 400-kVA transformer, enough to provide power to a village of 400 people, has around 6 kW of ohmic losses at full load. Improvement of the efficiency of the transformers increases overall efficiency of the power system and thus helps mitigate greenhouse gas emissions.

Significant effort has been made in improving the efficiency of transformers. Some of these efforts have targeted minimizing no load losses through improved design of the transformer by using more conductive materials and trying to reduce copper losses (Georgilakis 2009).

3.10.4.2 Loss Reduction by Reactive Power Compensation

Ohmic losses are proportional to the square of the electric current; therefore, by reducing the electric current one can reduces losses, while the useful power transferred is unaffected if higher voltage levels are applied. Thus an increase of voltage level can mitigate network losses.

Losses are higher at peak demand due to increased values of current. For example, on the island of Crete in 2001, the losses were 2% at low load and 3.3% at peak load (Thalassinakis and Gigantidou 2012, personal communication).

What should be taken into consideration is that electric current has two factors, one of active power P (i.e., the power that produces useful work) and the other of reactive power Q, which is necessary to create the electromagnetic field in electric machines but which does not produce any useful work. This is clearly shown in Figure 7, where complex power S is the vector of summation of P and Q. Increased reactive power increases the electric current and hence increases network losses.

Reactive power compensation is a common practice among utilities in order to reduce network losses and increase voltage stability of the network. Means of reducing the reactive power include the use of shunt capacitors with simple or more sophisticated – power electronics driven – switches.

3.10.4.3 Network Reinforcement for Access to Areas with Increased Renewable Energy Sources (RES) Potential and Weak Networks

Increased RES penetration results in greenhouse gases reduction. Quite often areas with rich RES potential are sparsely inhabited. Such areas may be windy areas, islands, or even deserts. In order to exploit this high RES potential, significant network infrastructure is required. The vast majority of network reinforcements refer to improved access to areas with high RES potential. Such are the plans for Euro-Mediterranean interconnections primarily aiming at the utilization of the excessive solar potential of the deserts. Building concentrated solar power (CSP) plants in the Sahara desert requires significant transmission system capacity and undersea DC cables (Desertec 2012). In China, there are areas with very favorable wind conditions but due to the distance from the centers of consumption, its exploitation requires significant efforts on building transmission lines (Jiang et al. 2011). Similar issues are faced in the United States, where many of

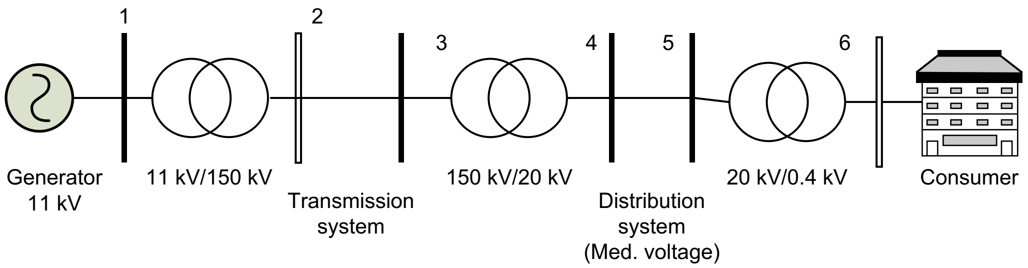

Figure 6 Typical structure of the network for meeting the demand of a consumer, focusing on transformers.

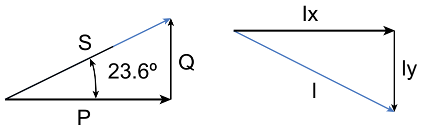

Figure 7 The triangle of active P and reactive power Q and the corresponding currents Ix and Iy.

the best wind resources are away from existing transmission corridors, and also facing the issue of who is going to pay for this reinforcement (Piwko et al. 2011).

The interconnection of Cycladic islands with the mainland of Greece (Hatziargyriou et al. 2007) is a relevant project ready to start construction while interest in interconnecting most of Greek islands with the mainland has recently been expressed by policymakers (Papadopoulos et al. 2007). The core idea behind the proposals for new interconnection projects is the exploitation of favorable wind power conditions of eastern Greece and the Greek islands.

Efficient management of existing network infrastructure could enable the simultaneous building of generation facilities and transmission networks. Suitable control schemes can be applied to alleviate network congestion due to increased RES penetration. In that way, most of the RES production can be fed to the grid even prior to the finalization of the transmission system expansion. The HTSO that manages wind parks in the northeast region of Thrace in Greece followed a similar methodology in order to avoid rejecting produced wind energy before the finalization of transmission system upgrades that are constructed for the UCTE-Turkey synchronous interconnection. In particular, the methodology followed was the introduction of 'interruptible contracts' and the continuous monitoring and control of the power flow through the congested corridors by issuing a set-point to each wind farm (WF) of the area to reduce its production, whenever system security was endangered. The control concept was applied according to the following rule: "The power flow through the interconnecting lines is not allowed to exceed a predefined security limit." This limit was calculated with respect to the N-1 security criterion according to the Grid Code regulations. In case of limit violation, the controller would send set-points to the WFs with interruptible contracts to reduce their production, if necessary.

The necessary power reduction was to be shared by all WFs with interruptible contracts. The control scheme was implemented using an autonomous system comprised of programmable logic controllers (PLCs) communicating to each other through two different and independent telecommunication lines. The existing SCADA system was utilized for monitoring and settlements if necessary. More technical information on this issue can be found in Kabouris and Vorunas (2004) and Kabouris and Michos (2005).

3.10.4.4 Distributed Generation

According to the European Commission, "Current grids have served well but will not be adequate in the future: grids must ensure secure and sustainable electricity supplies throughout Europe, take advantage of new technologies and comply with new policy imperatives and changing business framework" (SmartGrids 2006). A new era of grid planning has arrived that will integrate in an optimum way microproducers and microconsumers of power. DG will be a significant feature of the new energy system, well combined with the centralized system already in place.

Even though there is more than one definition of distributed generation, it is agreed that the following terms refer to the same idea: distributed, dispersed, decentralized, or embedded generation (Jenkins et al. 2000). Distributed generation is production sharing the following characteristics:

1. It is not centrally developed (from utility or administrator).
2. The power system operator does not schedule its production.
3. The installed capacity is below 50–100 MW.
4. It is connected to the distribution system either at medium voltage or at low voltage.

The driving forces for installing distributed generation include, among others, the increase in reliability, the use of local fuels (e.g., biogas), combined heat and power production to improve overall efficiency (Pecas Lopes et al. 2007), or the variability of renewable energy sources. The attractive financial environment (e.g., high remuneration prices for integrating PVs on buildings) is also one parameter leading to development of production installations near consumption. The units, either RES or conventional, usually used for this purpose can be classified from Figure 8.

Advances in each of these technologies can be found in various textbooks, either for the distributed generation (Jenkins et al. 2000; Willis et al. 2000) or in specific textbooks for each technology (Larmine and Dicks 2000; Soares 2007). Additionally, review articles on the advances in each technology have been published by various editors (Hansen and Hansen 2007; Kaisare and Vlachos 2012; Peppermans et al. 2005).

3.10.4.4.1 Microgrids

It is now well understood (Hatziargyriou et al. 2007), that DG cannot operate under the 'fit and forget' principle anymore, but some level of DG aggregation and control is required. Aggregation expands the DG benefits and can provide additional support to the operation of the electricity networks.

One of the potential methods of aggregation is the formulation of microgrids, which are low or medium voltage grids with distributed operation. Microgrids usually have storage devices such as flywheels, energy capacitors or batteries, and controllable loads such as water heaters or air conditioners that can be connected to the main power network or be operated autonomously in a coordinated, controlled way. Microgrids mostly not only operate interconnected to the main distribution grid, but also islanded in case of external faults.

In terms of power grids, a microgrid can be regarded as a controlled entity within the power system that can be operated as a single aggregated load. Given attractive remuneration it can be regarded as a small generator or even as an ancillary service to support the network. In terms of AC customers' energy services, microgrids deliver thermal and electricity needs to the customers, enhance local reliability of supply, and improve power quality by supporting voltage and reducing voltage dips. They are also considered a means of reducing emissions due to the reduction of network losses and potentially as a means of lowering costs of energy supply.

It is clear that in order to achieve these benefits, it is important to provide a coordinated decision making process, one that facilitates a balance between demand and supply from both distributed and centralized sources from MV distribution feeders. Description of this hierarchy in combination with the following two potential market policies for microgrids operation is provided by Tsikalakis and Hatziargyriou (2008). These two market policies foresee that microgrids maintain zero reactive power serving their own customers' needs and thus minimize cost; at the same time, microgrids buy and sell power to the grid aiming for profit maximization.

Such operation requires exchange of information between a central controller and the local controllers that may represent either a generation unit or a controllable load, regarding market prices of each controller. The implementation of such a scheme also can be made using software agents (McArthur et al. 2007).

Operation of microgrids can be further developed and control options can be designed in order to achieve some additional benefits like demand side bidding (participation of the loads in the market), participation in emissions markets (Tsikalakis and Hatziargyriou 2007), cooperation for voltage regulation within the microgrid (Geibel and Reimann 2011), coordination for black start capabilities (Pecas Lopes et al. 2005), and coordination for providing ancillary services to the upstream network (Joos et al. 2000).

Additionally, this coordinated operation and the fact that the capacity is increased in the proximity of the consumption can help significantly in the deferral of investments in electricity networks, especially at the distribution level (Gil and Joos 2006).

Microgrids can increase the already significant benefits in terms of economic operation, losses reduction, and emissions avoidance of distributed generation (Hatziargyriou et al. 2011; Costa and Matos 2009). Reduction in losses helps in further reduction of emissions.

Significant research on microgrids is being conducted all over the world in order to propose the most promising market

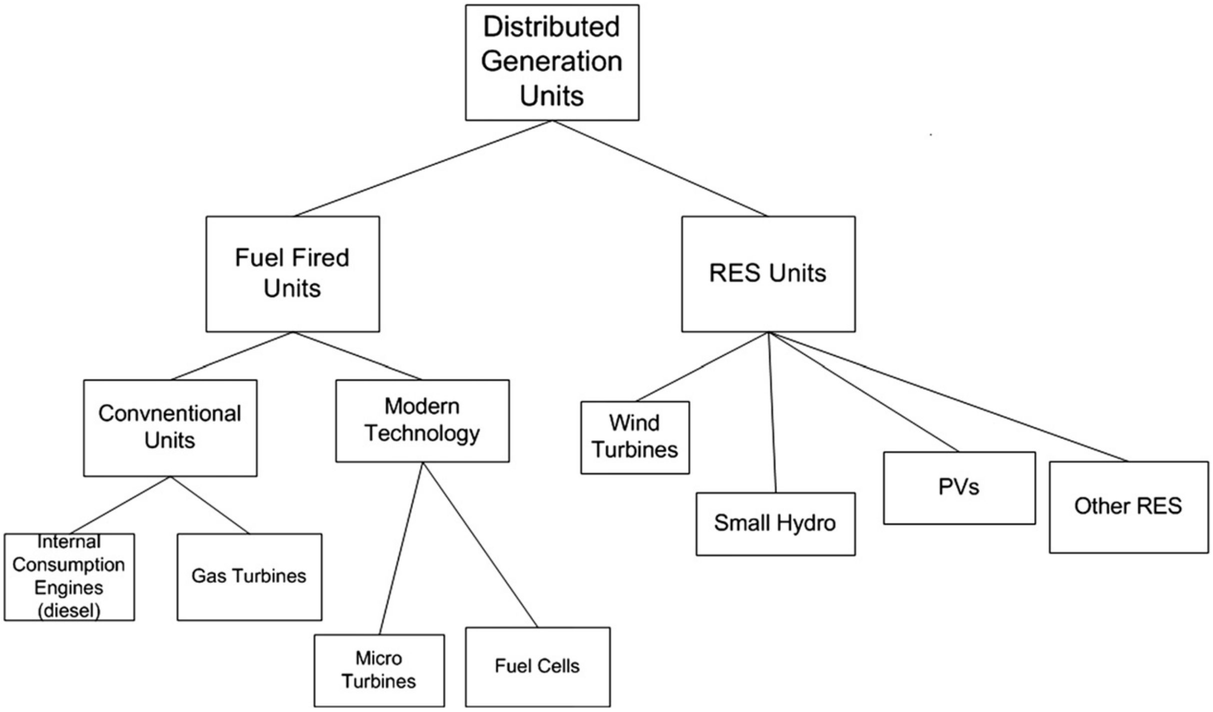

Figure 8 Classification of distributed generation.

operation schemes, to alleviate any potential technical problems like islanding operation with inverter-dominated networks, and to tackle regulatory issues (Kroposki et al. 2008; Satoshi 2007). Algorithms and hardware have been developed in order to implement new facilities from microgrids and some of them have been successfully tested in various test sites.

A more market-oriented control approach that does not require direct connection among the DG units, as do microgrids, is the one of virtual power plants (VPP) (Asmus 2010). Under the VPP operational framework, different DG units, which can be rather far away to be considered as a network neighborhood, can cooperate in order to operate as one market entity as if these units were one plant. This is why this approach is called *virtual power plant*.

Therefore, distributed generation and its coordinated operation either in microgrids or in VPP can provide substantial help in facing the problems of electricity networks related to human impact on climate variability or even help in mitigating the emissions related to electricity production.

3.10.5 Suggestions

In order to reduce vulnerability of networks to weather extremes, careful planning and locating of infrastructure should be made by incorporating all available information as regards the geography of climatic variability. Decision makers should also take into consideration that network infrastructures have a very long lifetime, thereby long-term climatic variations and especially sea level rise must be accounted for. Planners should also integrate criteria related to extreme weather effects, and countermeasures should be considered as part of the normal development of the network.

One tool of significant importance for this purpose is the use of geographical information systems (GIS) (Meehan 2011). This is of great help when building geographic models and calculating the exposure of segments to extreme whether conditions. Without the use of the current GIS software, these tasks would have been extremely burdensome or even impossible. More generally, GIS could improve and facilitate the planning and operation of transmission and distribution networks. Mapping via GIS can help in identifying outages even more quickly and thus more quickly restore any faulty equipment.

The physical capital of the energy system must be upgraded or planned according to adaptation measures described above. Specific measures can be taken to combat the effects of different climatic characteristics, like antiflood measures to avoid floods and landslides that can be integrated in the general upgrade of the equipment.

Appropriate human capital development is also required, that is, the personnel of utilities should be trained adequately to be able to face extreme weather or catastrophic events (e.g., landslide). Many utilities already have such training or other weather-related emergency plans, but these should be revisited. Training and hiring personnel may increase operational expenses but these expenses may be very little compared to the benefits from the avoidance of a massive destruction of a substation or other related infrastructure.

In addition to personnel, automation of power networks, especially distribution systems, can help in quickly identifying the risky events on the networks. The exact timing of finding a fault may be crucial for the protection of the rest of the equipment. Moreover, use of high voltage DC networks could potentially help in nonpropagating faults in the transmission systems to neighboring utilities. The connection between two AC networks is unstable because of phase differences. Power exchange between two AC networks that are not synchronous is feasible by means of high voltage direct current (HVDC) lines (e.g., England–France). An AC network connected with neighboring grids through HVDC links may, in the worst case, lose the power transmitted over the link in case the neighboring grid goes down. The HVDC transmission will act as a firewall against cascading disturbances (Arrowsmith 2009) and is thus considered as a potential solution for major interconnections.

Overall, it can be concluded that a more extensive use of distributed generation can help in reducing the number of customers affected by an outage and decrease the restoration time. Distributed generation is also considered an essential characteristic of a low carbon energy system and as a result the incorporation of decentralized planning can prove a win–win situation as regards mitigation and adaptation to climate variability.

Glossary

Water scarcity An imbalance between water supply and water demand in a given region/community.

Renewable energies Energy that comes from natural resources such as sunlight, wind, waves, tides, and geothermal heat, which are renewable.

Seawater desalination The removal of salts or other constituents through thermal or filtration processes to generate potable water.

Concentrating solar power The harnessing of solar energy by directing/concentrating incoming radiation on a line- or point-collecting device through reflective surfaces.

Cogeneration of electricity and desalinated seawater The generation of electrical energy and potable water in an integrated installation/plant and utilizing renewable/solar energy.

3.11.1 Introduction

Water and energy are two essential ingredients sustaining life on this planet. Both quantities are also intractably linked through a number of critical conditions, particularly when one considers manufactured energy sources and potable water. Examples for these linkages include coolant water needed in electrical power plants or energy required for pumping and transporting drinking water in distribution networks, to name but two (see, e.g., Schnoor 2011; Siddiqi and Anadon 2011). Of course, there are links to other important issues, as well. Water is seen as the primary rate-limiting factor for food production. Electricity

http://dx.doi.org/10.1016/B978-0-12-384703-4.00320-8

demand is likely to grow significantly in light of increasing needs for space cooling in order to limit the adverse effects of urban heat island-induced human health problems.

On a more general note, recent decades have seen rapidly increasing multiple pressures on water-, energy-, and food security, an issue that has been described as the Water, Energy and Food Security Nexus (Hoff 2011). The underlying driving forces of this Nexus include a variety of more recent developments including a growing demand on natural resources accompanied by their degradation caused by overexploitation, a rapidly evolving urbanization, and the emergence and growth of Mega Cities, which lead to increasing contaminant emissions and growing volumes of waste products on a limited spatial scale. An ongoing trend toward globalization, particularly in the private sector, with associated tendencies to externalize resource use and degradation to distant regions is another driving force underlying the Water Energy and Food Security Nexus. Finally, exacerbating some of the above drivers, changes in global and regional climate conditions increasingly require mitigation, adaptation strategies, and measures at an accelerating pace. An important characteristic of these pressures is their strong interlinkage, which lead to feedback that drives environmental and human systems to critical thresholds and tipping points that seriously affect access to water, energy, and food.

This chapter concentrates on a subset of the Water, Energy and Food Security Nexus by addressing more specifically the already mentioned linkages between water and energy; that is, the 'Water energy nexus' (see Hoff 2011; Schnoor 2011). In particular, I will consider two issues: (1) electricity generation and its need for water (Figure 1(a)) and (2) the energy demand for seawater desalination, which typically accounts for more than one third of the total cost (Figure 1(b)). Moreover, I will address options and innovative technologies to enable the reduced use of both resources as they relate to issues (1) and (2) above.

The chapter starts out with brief reviews on renewable energy sources (RES) and water availability, water supply, and water demand. This is followed by a concise description of desalination technologies and their recent advance. Next, I concentrate on a novel, but increasingly employed technology to harness solar power in solar-thermal electricity generation: the concentrating solar power (CSP) technology. Finally, I introduce and describe a new technological development that will enable the cogeneration of electricity and desalinated seawater, employing CSP as the ultimate energy source.

3.11.2 Renewable Energy Sources

Renewable energy sources (RES), for example, wind power, though known throughout the history of humans, represent a relative recent development when it comes to harnessing renewables on an industrial scale. The current use of renewables in the overall global energy portfolio is relatively limited. Renewables (both combustible as well geothermal, solar, wind, etc.) accounted for no more than 10.7% of the total primary energy supply on a global level in 2008 (IEA 2010). The major reason for such a relatively small fraction of renewables lies in the still higher prices of these energies, compared with conventional sources, that is, oil, gas, and nuclear (Figure 2). As can be seen, particularly photovoltaics (PV) comes at a price tag four to five times higher than conventional energies. However, as can be observed as well, prices for onshore wind energies already today come close to conventional prices.

Thus, it is expected that the use of renewable energy sources (RES) will be increasing by significant growth rates over the coming decades. In the European Union (EU), the gross final renewable energy consumption will more than double from 98.7 Mtoe (1 toe equals 41.868 GJ or 11.63 MWh) in 2005 to 2445.6 Mtoe with average growth rates of 6.8 and 6.2 for the periods 2005–10 and 2015–20, respectively (Beurskens and Hekkenberg 2011). In a recent report, the German Advisory Council on the Environment (2011) comes to the conclusion

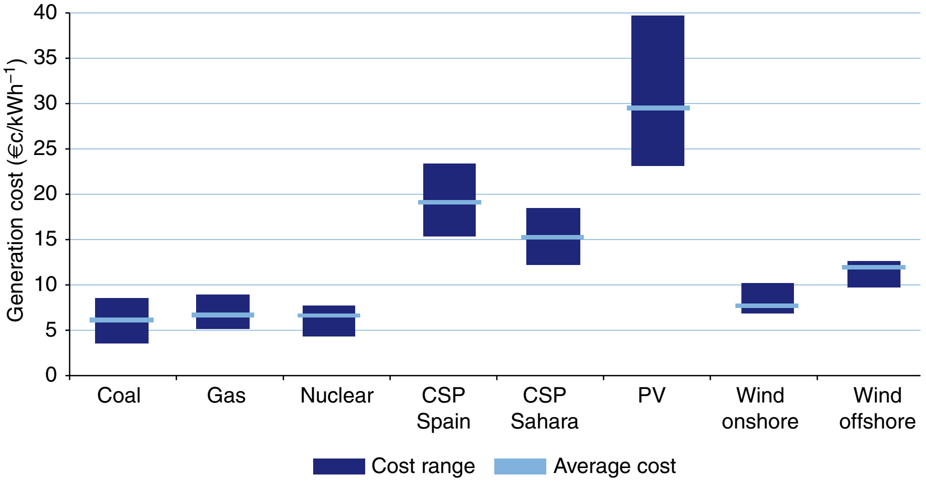

Figure 2 Typical levelized costs of electricity generation. Source: PricewaterhouseCoopers, Potsdam Institute for Climate Impact Research, International Institute for Applied Systems Analysis, and European Climate Forum, 2010: *100% Renewable Electricity – A Roadmap to 2050 for Europe and North Africa*, 144 pp. [Available online at http://www.pwc.co.uk/pdf/100_percent_renewable_electricity.pdf.]

that a secure and affordable wholly renewable electricity supply is well within reach, particularly when combined with enhanced energy efficiency measures.

RES come in different forms and varieties (for an overview on various RES, see, e.g., Beurskens and Hekkenberg 2011; Edenhofer et al. 2011; Schiermeier et al. 2008). In the following, a brief compilation of renewable energy sources with an emphasis of their use for electricity generation will be given.

3.11.2.1 Hydropower

Hydropower harnesses the potential energy of water moving from higher to lower elevations. It is used primarily to generate electricity. Hydropower projects encompass dam projects with reservoirs, run-of-river, and in-stream projects and cover a continuum in project scale (Edenhofer et al. 2011). Hydropower represents the largest source of renewable electricity in Europe, supplying 60% of Europe's total renewable energy. Hydropower technologies are mature and, depending on the location of the installation, hydropower can be cost-competitive even with coal (PricewaterhouseCoopers et al. 2010). Dammed reservoirs for hydropower generation often enable their uses for other purposes including the supply of drinking water, irrigation, flood and drought control, and navigation (Edenhofer et al. 2011).

Because hydropower is a dispatchable form of energy, it is especially important for a renewables-only power system. When combined with pump reservoirs, excess power can be stored for later times, when water supply may be limited. However, two factors limit the major continued expansion of hydropower. First, future capacity is limited by geographic factors and the availability of space for dam storage. This notwithstanding, the economic potential of hydropower is about 30% greater than current utilization and about double the current utilization in western and southeastern Europe, respectively. Second, hydropower utilization is facing significant environmental concerns such as the loss of land, habitat, and the displacement of settlements, which limits its development in many countries.

3.11.2.2 Wind Energy

Wind energy utilizes the kinetic energy of moving air through wind turbines located on land (onshore) or in seawater or freshwater (offshore). Onshore wind energy technologies are proven technologies and are deployed on a large scale. Although offshore wind energy technologies pose significantly larger challenges in their employment, they also have greater potential for continued technical advancement. Electricity generation through wind power is both variable and, to some degree, unpredictable. However, experience and detailed studies from many regions have shown that the integration of wind energy generally poses no insurmountable technical barriers (Edenhofer et al. 2011).

Wind power has been the fastest growing form of renewables in Europe. At the end of 2007, it accounted for 52 GW of installed generating capacity, supplying 3.8% of the EU-27 total electricity consumption. It represents the second largest share of renewable electricity in Europe, after hydropower. One of the major reasons for the growth in wind power utilization is that it is currently the lowest cost renewable energy source (Figure 2). The development of offshore wind installations has been low in comparison with onshore wind, mainly because the costs are, at present, higher than for onshore wind at good sites. It has been estimated that it would be possible to obtain approximately 1000 TWh year^{-1} of onshore wind at a cost of less than €0.05 kWh^{-1}, and about 2500 TWh year^{-1} at a cost of less than €0.07 kWh^{-1} for OECD Europe as a whole. In practice, however, it will not be feasible to develop all of the sites that are suitable for wind power for various reasons (e.g., opposition by the local population). As a consequence of the intermittency of wind, achieving high penetration of wind power would require significant long-distance power transmission lines, spreading local wind conditions over a continental scale (PricewaterhouseCoopers et al. 2010).

3.11.2.3 Solar Energy

Solar energy technologies harness the energy of solar irradiance to produce electricity. Currently, there are principally two technologies employed: photovoltaics (PV) and concentrating solar power (CSP) technologies. PV generates electricity using the conducting properties of certain chemicals most importantly silicon, through the photo-electric effect. CSP makes use of reflectors to focus sunlight on a small area, in order to generate steam that powers a thermal electric plant (see below for more details). In addition to electricity generation, solar power is employed to produce thermal energy (heating or cooling, either through passive or active means), to meet direct lighting needs and, potentially, to produce fuels that might be used for transport and other purposes. The maturity of solar technologies ranges from the research and development stage (e.g., fuels produced from solar energy), to relatively mature technologies (e.g., CSP), to mature (e.g., passive and active solar heating, and wafer-based silicon PV). Many but not all of the technologies are modular in nature, allowing their use in both centralized and decentralized energy systems. However, particularly CSP technologies achieve economical feasibility only at a power capacity of a few tens of megawatts (see below). Solar energy is variable and, to some degree, unpredictable and solar irradiance varies significantly with geographic location (Figure 3). However, the temporal profile of solar energy output correlates relatively well with energy demands (Edenhofer et al. 2011; PricewaterhouseCoopers et al. 2010).

Photovoltaics has been growing quickly, although it still represents only 9 GW of total capacity in Europe. While in 2002, there were 550 MW of new PV cells installed; in 2007 this capacity had grown to more than 3 GW. PV, however, has two major constraints that somewhat limit its application: the cost of PV cells and the intermittency of solar irradiation and thus power generation. PV currently costs about €0.22–0.39 per kWh (Figure 2), depending on location. Almost all of this is comprised of capital costs. While unit prices for PV cells have been falling and will continue to do so by as much as 50% within a few years, this would still not make PV competitive with other technologies. With regard to the intermittency of PV, power is only generated during daylight and there are no storage options available. Thus, cloudiness and seasonality influence the amount of power generated (PricewaterhouseCoopers et al. 2010).

With regard to CSP, there are several technology variants in use (for more details, see the later section on CSP below). The first commercial plants in operation were built in the United States (410 MW) and Spain (100 MW). Globally, there are now more than 45 new CSP projects under development. These are projected to generate 5000 MW in North America, 2500 MW in Europe, more than 500 MW in North Africa, and 2400 MW elsewhere (PricewaterhouseCoopers et al. 2010).

3.11.2.4 Bioenergy

Bioenergy can be generated from various forms of biomass, including wood, agricultural, and livestock residues; short-rotation forest plantations; energy crops; the organic components of municipal solid waste; and other organic waste streams. Through a variety of processes, these materials can be directly used to produce electricity or heat. They also can be used to create gaseous, liquid, or solid fuels. The range of bioenergy technologies is broad and the technical maturity varies substantially. Bioenergy technologies are being applied in centralized and decentralized settings. The traditional uses of biomass in developing countries (mainly for cooking and heating) are the most widespread current applications. Bioenergy projects usually depend on local and regional fuel supply availability, but recent developments show that solid biomass and liquid biofuels are increasingly traded internationally (Edenhofer et al. 2011).

The burning of biomass for electricity generation can be competitive with coal. When using the resulting waste warmth for district heating, total efficiencies of bioenergy production can reach 85–90%. In combination with district heating, biomass is another dispatchable form of renewable power, because it relies on a storable fuel stock. The main concern with biomass is the availability of fuel stock to sustain large scale utilization. Finding sufficient land and water to grow enough material could become problematic and has been discussed extensively (see, e.g., Edenhofer et al. 2011). In many parts of the world, growing crops dedicated to biomass production can lead to higher net carbon emissions than fossil fuel burning because of the emissions associated with land clearings. There also are concerns about the impact of biomass production on agriculture, water use, and food prices (PricewaterhouseCoopers et al. 2010).

3.11.2.5 Geothermal Energy

Geothermal energy utilizes the accessible thermal energy from the earth's crust. Heat is extracted from geothermal reservoirs using wells ('deep geothermal') or other means including pipes that are deposited close to the surface and heat pumps ('shallow geothermal'). Two basic types of geothermal reservoirs are distinguished: (1) hydrothermal reservoirs, which are naturally sufficiently hot and permeable, and (2) enhanced geothermal reservoirs, which are sufficiently hot but need to be improved with hydraulic stimulation systems (EGS). Once at the surface, fluids of various temperatures can be used to generate electricity or can be used more directly for applications that require thermal energy. This includes (1) district heating or (2) the use of lower-temperature heat from shallow wells for geothermal heat pumps that are used in heating or cooling applications. Hydrothermal power plants and thermal applications of geothermal energy are mature technologies, whereas EGS projects are in the demonstration and pilot phase while also subject to continued research and development. When used to generate electricity, geothermal power plants typically offer constant output (Edenhofer et al. 2011).

While geothermal power has progressed nicely and in some places (such as Iceland) is commercially viable, concerns about the safety of geothermal energy generation have been discussed recently, after geothermal plants apparently triggered local earthquakes in Switzerland and Germany. This calls for additional and thorough studies to be undertaken (PricewaterhouseCoopers et al. 2010).

3.11.2.6 Ocean Energy

Ocean energy is derived from the potential, kinetic, thermal, and chemical energy of seawater, which can be transformed to provide electricity, thermal energy, or potable water. A wide range of technologies are possible, including (1) barrages for tidal range utilization, (2) submarine turbines for tidal and ocean currents, (3) heat exchangers for ocean thermal energy conversion, and (4) a variety of devices to harness the energy of waves and salinity gradients (see, e.g., Frigaard et al. 2008). Ocean technologies, with the exception of tidal barrages, are at the demonstration and pilot project phases and many require substantial additional research and development activities. Some of the technologies have variable energy output profiles with differing levels of predictability (e.g., wave, tidal range, and current), while others may be capable of near-constant or even controllable operation (e.g., ocean thermal and salinity gradient) (Edenhofer et al. 2011).

3.11.3 Water and Water Scarcity

Of all the water on this planet, totaling 1400×10^9 km^3, only 35×10^6 km^3 or 2.5% of it is consumable by humans as potable water. Of this fraction, 68.9% resides as snow, ice, or permafrost in the cryosphere, leaving 31.1% of the freshwater resources (or only 0.78% of the total water on earth) as water accessible to mankind. Despite this apparently small number (i.e., 0.78%), the total accessible freshwater on earth amounts to a quite impressive volume of 10.85×10^6 km^3. However, decades of unsustainable management have led to water shortages that have reached critical levels in many regions of the world (see below). Globally, humans appropriate more than 50% of all renewable and accessible freshwater for their use, while billions still lack the most basic water services highlighting the shortcomings in reaching the UN Millennium Development Goals with regard to the supply of potable water and sanitation (United Nations 2010).

This brings up questions related to the overall supply and the demand for potable water and their spatial and temporal distributions, which will be dealt with in the next section. As already indicated, water scarcity is an issue of increasing importance in some regions of the world and the prospects of climate change tend toward exacerbating these problems. This will be briefly discussed in Section 3.11.3.2.

Although not exclusively so focussed, the following sections will emphasize European conditions and characteristics.

3.11.3.1 Water Availability, Supply, and Demand

While the global volume of available freshwater amounts to 10.85×10^6 km^3, the total freshwater resources across Europe on an annual basis amount to 2270 km^3 year^{-1}. Of this volume, only 13% represent water abstracted from underground aquifers, suggesting that there is sufficient water available to meet demand. This represents only a relatively small proportion of its renewable freshwater resource, which suggests that there is sufficient water available to meet demand (EEA 2009). This notwithstanding, problems of an insufficient supply of potable water arise in many regions: this is in many cases due to an imbalance between water abstraction and availability, which is primarily driven by a mismatch between the distribution of people across Europe and the availability of water. In some locations across Europe, this is exacerbated by excessive abstraction rates.

This is by no means a European problem only. Figure 4 illustrates the availability of freshwater for human consumption on a global level. As can be seen, the volume of drinking water per person and year varies widely, with northern Africa and sub-Saharan Africa representing regions of scarcity, particularly. This reflects to a significant extent the distribution of precipitation on our planet because precipitation represents one of the primary sources of freshwater replenishment.

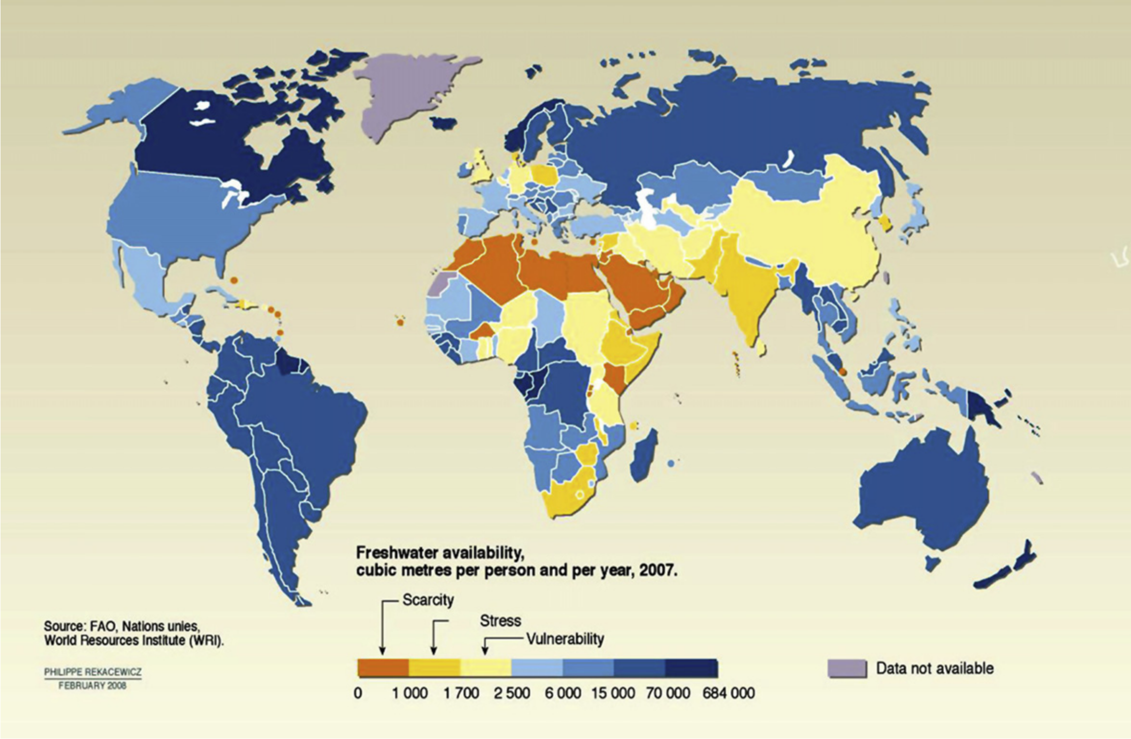

Figure 4 Global freshwater availability for human consumption in 2000. Source: UNEP-GRID, 2008: *Vital Water Graphics, Arendal, Norway.* [Available online at http://www.unep.org/dewa/vitalwater/index.html.]

However, mismanagement, waste, and contamination of freshwater sources in many parts of the world contribute to more rapid exhaustion of available resources than consumption alone.

Sources of freshwater supply include surfacewater and groundwater, water stored in cryospheric reservoirs (snow, ice, and permafrost), and also water produced through seawater desalination, collected rainwater, and reused or processed wastewater. Of the latter, I will only consider desalination in subsequent sections of this chapter.

In Europe, surface water, that is, water in rivers, lakes, and surface reservoirs represents the primary source for the energy and agricultural sectors as well as for industry, whereas groundwater is the predominant source (about 55%) for public water supply owing to its generally higher quality than surface water (Figure 1(a)). For agriculture, however, the role of groundwater as a source is probably underestimated because of illegal abstraction from private wells (EEA 2009). Reservoirs, that is, water bodies created mainly by damming rivers, represent a common means to ensure a sufficient level of water supply particularly in times of prolonged droughts. Even though not in terms of total volume, the sheer number of dams constructed in Cyprus in the 1970s and 1980s reflect the strong desire of the then governments to ensure adequate water security for the country in anticipation of growing demand and decreasing replenishment through precipitation (Figure 5(a)). However, interannual changes in precipitation rates have resulted in varying volumes of water available to the agricultural sector, the main benefactor of the stored dam water in Cyprus (Figure 5(b)).

Water stored in snow and ice is of significant importance for many countries, particularly those at higher latitudes and/or in countries with high mountain ranges that are the precondition for the formation of glaciers and ice caps. The Alps, which have often been called the 'water tower of Europe,' currently provide 40% of Europe's freshwater (EEA 2009). Changes to these stores result in significant impacts on the availability of water, both seasonally and in the longer term.

Groundwater serves as main source of drinking water throughout Europe. However, over-abstraction, contamination by various sources, and intrusion of seawater in coastal aquifers have resulted in significant risks to groundwater resources in many European countries (Figure 6). As can be seen, about 80% of the groundwater is 'at risk' in Cyprus.

However, the future fate of rainfall or precipitation, which represents the principal natural replenishment of surfacewater and groundwater reservoirs, poses a risk of another dimension. One of the principal findings of climate projections, based on numerical global climate models of the Intergovernmental Panel on Climate Change (IPCC), is that regions that are currently well supplied by precipitation are predicted to have increasing rates of rainfall in the coming decades, whereas regions already suffering from decreasing trends of water supply by precipitation are predicted to experience even lesser amounts of rainfall. As simulated in multi-decadal model projections, countries and regions along the mid-latitudinal belts in general and in those of the Mediterranean Basin, in particular, may have changes in regional climate statistics, resulting in significant reductions in precipitation over the coming decades (e.g., Meehl et al. 2007).

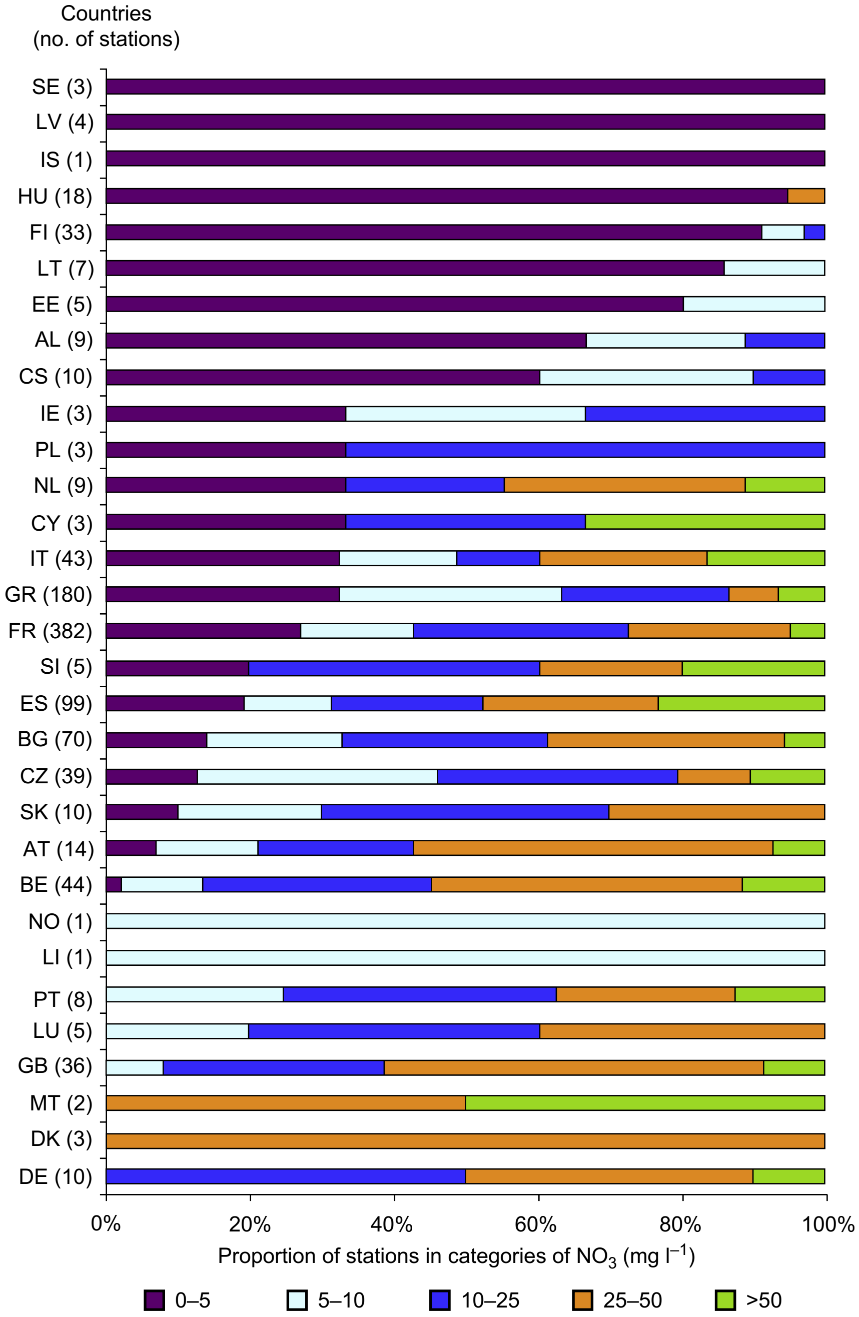

Figure 6 Present concentration of nitrate in groundwater bodies in selected European countries. Source: European Environment Agency, 2008: *Present Concentration of Nitrate in Groundwater Bodies in European Countries.* European Environment Agency. [Available online at http://www.eea.europa.eu/data-and-maps/figures/present-concentration-of-nitrate-in-groundwater-bodies-in-european-countries.]

However, it needs to be recognized that the global climate models have not proved fully satisfactory in multi-decadal predictions of changes in regional climate statistics (see, e.g., Pielke and Wilby 2012). Indeed, even skillfully predicting (in a hindcast mode) regional climate statistics over the last few decades has not been adequately achieved (see, e.g., Anagnostopoulos et al. 2010; van Oldenborgh et al. 2012; Xu and Yang 2012). Fyfe et al. (2011) found that for longer term decadal hindcasts they had to correct for systematic long-term trend biases. Xu and Yang (2012) concluded that without tuning from real world observations, the model predictions are in significant error in terms of both temperature and precipitation. Work by Anagnostopoulos et al. (2010) revealed that local multi-decadal climate model projections do not correlate well with observed measurements, and, moreover, that the correlation at a large spatial scale, for example, the contiguous United States, is even worse than at the local scale.

Figure 7 Increase in annual water demand for the period 2005–30 in billion cubicmeter and in percent. Source: 2030 Water Resources Group, 2009: *Charting our Water Future – Economic Frameworks to Inform Decision Making*, 198 pp.

With regard to the EU, but also largely reflecting global patterns, the consumption of both surface and groundwater is driven by four main economic activities: cooling in electricity production; public water supply; the manufacturing industry; and agriculture, forestry, and fishing. For the EU, overall consumption patterns amount to 44% of the total abstracted water for energy production, 24% for agriculture, 21% for public water supply, and 11% for industry (Eurostat 2011; c.f., Figure 1(b)). However, there are significant differences in abstraction levels for each of the sectors, depending on geographical and geoclimatic conditions. Figure 7 illustrates increases in water demand in absolute numbers as projected for the period 2005–30 for selected countries/regions of the world (2030 Water Resources Group 2009). As can be seen, water demand will grow substantially in order to satisfy the increasing need of the agricultural and – in the case of China – industrial sectors. Given these figures, in conjunction with what has been said regarding possible changes in regional climate statistics, water scarcity in already water-scarce regions is likely to increase. This will be briefly discussed in the next section.

3.11.3.2 Water Scarcity

The term 'water scarcity' is defined by the UN-Water initiative as "… the point at which the aggregate impact of all users impinges on the supply or quality of water under prevailing institutional arrangements to the extent that the demand by all sectors, including the environment, cannot be satisfied fully. Water scarcity is a relative concept and can occur at any level of supply or demand. Scarcity may be a social construct (a product of affluence, expectations, and customary behavior) or the consequence of altered supply patterns – stemming from climate change for example …" (UN-Water 2005). More 'practical' definitions of this and related terms are given in the Human Development Report 2006 (United Nations Development Programme 2006): water stress depicts the availability of less than 1700 m^3 per person and year, water scarcity of less than 1000 m^3 per person and year and absolute water scarcity of less than 500 m^3 per person and year.

If the related subset of the current IPCC climate change projections is correct (Meehl et al. 2007), almost half of the world's population will be living in areas of high water stress by 2030, including between 75 million and 250 million people in Africa. In addition, water scarcity in some arid and semiarid places would displace between 24 million and 700 million people (UN-Water).

Information in the Human Development Report (United Nations Development Programme 2006) confirms this projection. The report indicates that by 2050 about 5.5 billion people will suffer from either water stress or water scarcity.

The current situation with regard to the global distribution of water stress and waters scarcity is depicted in Figure 4. As can be seen, all of the northern African countries and most of the Middle Eastern countries (including Cyprus) suffer from water scarcity or water stress. As a remedy to secure the supply of drinking water to their citizens, many of the aforementioned countries have introduced seawater desalination in recent years. Some countries, for example, Cyprus (Water Development Department Cyprus 2010) and Israel, are determined to secure the entire demand for potable water through desalination of seawater (in the following abbreviated as DSW). The next section will briefly describe the current state of DSW technologies, their energy demands, and some of the new developments.

3.11.4 Desalination of Seawater

In light of the discussions that follow, we will concentrate on two classes of desalination, that is, membrane-based methods, specifically the Reverse Osmosis (RO) technology, and thermal desalination methods, specifically multiple effect distillation

(MED). For a more general overview see, for example, NAS (2008) or Trieb et al. (2007).

3.11.4.1 Brief Review of RO and MED Desalination Technologies

3.11.4.1.1 Multieffect Desalination

A multieffect desalination (MED) evaporator consists of several consecutive cells (effects) maintained at decreasing levels of pressure (and temperature) from the first (hot) cell to the last one (cold). Each cell mainly consists of a tubes bundle. The top of the bundle is sprayed with the seawater make-up that then flows down from tube to tube by gravity. Heating steam is introduced inside the tubes. Since tubes are cooled externally by make-up flow, steam condenses into distillate (freshwater) inside the tubes. At the same time, seawater warms up and partly evaporates by recovering the condensation heat (latent heat), because of the fact that evaporating seawater slightly concentrates when flowing down the bundle and gives brine at the bottom of the cell. The vapor raised by seawater evaporation is at a lower temperature than the heating steam. However, it can still be used as heating media for the next effect whereby the process is repeated. The decreasing pressure from one cell to the next one allows brine and distillate to be drawn to the next cell, wherein they will flash and release additional amounts of vapor at the lower pressure. This additional vapor will condense into distillate inside the next cell. This process is repeated in a series of effects. In the last cell, the produced steam condenses on a conventional shell-and-tube heat exchanger. This exchanger, called 'distillate condenser,' is cooled by seawater. At the outlet of this condenser, part of the warmed seawater is used as make-up of the unit; the other part is rejected to the sea. Brine and distillate are collected from cell to cell until the last one, from where they are extracted by centrifugal pumps.

The main advantages of a MED system can be summarized as follows:

- Very low electrical consumption (<1.0 kWh m^{-3})
- Operates at low temperature (<70 °C) and at low concentration (<1.5)
- Produces steadily high purity distillate
- Does not need complex pretreatment of seawater and are tolerant to variations of seawater conditions
- Is highly reliable and simple to operate
- Reduces civil works cost
- Is simple to install
- Has a low maintenance cost
- Operates 24 h a day with minimum supervision
- Ideal for coupling with power plants
- Can be adapted to any heat source
- Allows very high thermal efficiencies and savings in fuel costs (NAS 2008)

If high-pressure steam is available, for example, from a power plant, the efficiency of a MED plant can be further enhanced by using a steam ejector. The high-pressure steam is the so-called motive steam, which provides the energy for recompression of the product vapor from the evaporator of a given effect. The vapor leaving the thermocompressor, which will be at an intermediate pressure level, is again used as driving heat for the first evaporator. A MED with thermal vapor compressor can benefit from heat at higher temperatures, without increasing the top brine above the critical scaling temperature of 65–70 °C. There are very simple and robust skid mounted units with smaller size steam piping available. However, MED-TVCs have a lower thermodynamic efficiency than a simple MED. A steam transformer is mandatory if clean distillate in the first cell is required. Recently, steam compressors with low motive steam pressure (1–2 bar abs.) have been developed. All systems are quite robust. The operation is simple and fault tolerant to a very high degree.

3.11.4.1.2 Reverse Osmosis

The reverse osmosis (RO) technology is based on a membrane separation process in which the water from a pressurized saline solution is separated from the solutes (the dissolved material) by flowing through a membrane. In practice, the saline feed water is pumped into a closed vessel where it is pressurized against the membrane. As a portion of the water passes through the membrane, the remaining feed water increases in salt content. At the same time, a portion of this feed water is discharged without going through the membrane.

Without this controlled discharge, the pressurized feed water would continue to increase in salt concentration creating problems such as precipitation of super saturated salts and increased osmotic pressure across the membranes.

An RO system is made up of the following basic components:

- Pretreatment
- High-pressure pumps
- Membrane assembly and
- Posttreatment

The past 10 years have been significant ones for the RO process. Although the process has not fundamentally changed in concept, there have been steady and continuous improvements in the efficiency of the membranes, energy recovery, energy reduction, membrane life, control of operations, and operational experiences. Currently most of implemented seawater desalination plants use RO technology. Systems of 300 000 m^3 day^{-1} and recently even larger have been built and are in operation in many parts of the world. Desalted water cost decreased from \$2.0 to 0.5 m^{-3} and worldwide capacity is continuously increasing (Trieb et al. 2009; UNEP/MAP/MED POL 2003).

3.11.4.2 Energy Demand for Desalination

Seawater desalination, regardless of the technology employed, is a relatively energy intensive process. This is why desalination costs are strongly correlated with energy prices (NAS 2008).

Energy requirements for desalination plants depend on the following:

- Volume of water produced
- Salinity and temperature of the feed water
- Quality of the water produced
- Desalination technology used

In the following, I will present brief estimates for the energy needs of MED and the RO technology, respectively.

3.11.4.2.1 Energy Demands for MED

Semiat (2008) provides a comprehensive review of the energy requirements for MED technologies. The simplest desalination technique, single-stage evaporation of seawater, consumes a tremendous amount of energy, around 650 $kWh_t\ m^{-3}$ of product, depending slightly on the evaporation temperature (the unit kWh_t refers to thermal energy). The MED technology has overcome this obstacle by reusing energy consumption through multiple stages (see above). Thermal energy based on fuel consumption in typical 'single-purpose' plants is in the range of 40–65 $kWh_t\ m^{-3}$ of product for MED, and the work equivalent of these energy consumptions, based on an efficiency of about 45% in a modern power station, is 18-30 $kWh_e\ m^{-3}$. Around 1.2–4.5 $kWh_e\ m^{-3}$ of pumping energy must be added to these quantities. In his review, Semiat (2008) presents numbers on the combined energy demand of MED plants ranging from 6–12 to 5–65 $kWh_e\ m^{-3}$ as given by different authors.

The energy consumption of thermal desalination processes may be reduced considerably in 'double-purpose' plants, which utilize heat released by the turbine condensing steam to provide the primary thermal energy required for a MED desalination process. Because high efficiency of electrical energy production requires a low steam condensation temperature close to the ambient temperatures, the back-pressure of the turbine is consequently increased to provide an adequate heating steam temperature in the range of 70–120 °C. Given this alternative, the total energy consumption for MED technologies that utilize exiting steam at various temperatures and including pumping energies in the process amounts to

- 4–5.6 $kWh_e\ m^{-3}$ for a GOR (GOR or 'gained output ratio' is defined as the ratio of the number of tons of water produced per ton of steam as energy invested) of 10 and a temperature working range of exiting steam of 70–35 °C
- 5 $kWh_e\ m^{-3}$ for a GOR of 16 and a temperature working range of exiting steam of 100–35 °C (Semiat 2008).

The estimation given appears to be too low because energy losses to the environment may be high and may be altered based on the heat recovery equipment employed and thus the capital investment needed in building the plant. This results in total energy consumption closer to 13 $kWh_e\ m^{-3}$ including pumping, and the real values probably lie between this and the values given above (Semiat 2008).

3.11.4.2.2 Energy Demands for RO

Owing to the development of large pumps that use modern efficient turbines and other energy recovery devices and thereby achieve efficiencies approaching approximatly 90%, the specific energy for RO desalination has decreased significantly over the past decade and is approaching the theoretical thermodynamic minimum. The newer devices, known as turbochargers, pressure exchangers, or work exchangers, names adopted by different manufacturers, represent efficient ways of recovering the energy content of the high-pressure concentrate leaving the membrane module (Semiat 2008). The turbines convert the concentrate pressure into the velocity of a jet that spins a wheel, which is used either to reduce the power consumption of the motor driving the pump or to boost the pressure of the feed to a second stage. Taking into account the additional pumping requirements involved in conveying the feed, concentrate, and permeate steam, the overall energy needs are less than 3.7 $kWh_e\ m^{-3}$ of product in RO seawater desalination (Semiat 2008).

Thus, the overall energy requirements appear to be much less for RO plants in comparison with MED plants. However, as explained above, MED technologies enable the utilization of process or waste heat from other processes, for example, electricity generators, which favor MED over RO when considering the coupling of electricity generation and seawater desalination. This will be described in more detail later. However, before addressing this issue, the following section presents a review of solar-thermal electricity generation.

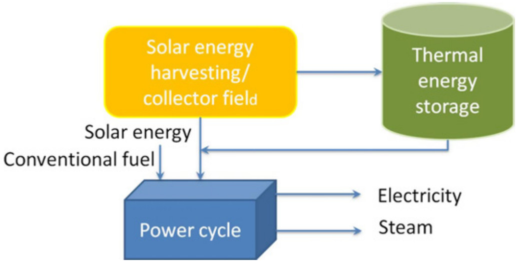

Figure 8 Main elements and principle of a CSP plant. Source: After Trieb, F., and Coauthors, 2009: *Combined Solar Power and Desalination Plants: Techno-Economic Potential in Mediterranean Partner Countries – WP1: Technology Review and Selection of CSP and Desalination Configurations adapted for Application in the Southern and Eastern Mediterranean Region*; Final Report, 117 pp.

3.11.5 Concentrating Solar Power

3.11.5.1 General Principles

Concentrating solar power (CSP) plants represent solar-thermal facilities for electricity generation. They combine the capability of a thermal energy storage medium with alternative hybrid operations employing either solar energy harvested or fossil or biofuels (Figure 8). This enables – at least theoretically – the provision of electrical power on demand, 24 h a day and 365 days a year. The core element of a CSP plant is a field of large mirrors reflecting the captured solar rays to a small receiver element, thus concentrating the solar radiation intensity by about 80 to several 100 times and producing high temperature heat at several 100 to over 1000 °C. This heat can be either used directly in a thermal power cycle based on steam turbines, gas turbines, or Stirling engines, or accumulate in a heat storage medium such as molten salt, concrete, or phase-change material to be delivered at a later point to the power cycle for nighttime operation (see the following).

The principle of operation of a concentrating solar collector and of a CSP plant is given in Figure 8, which illustrates both the hybrid operation option of a CSP plant with solar and other energy and the option of either using the energy harvested directly in the power cycle or to transfer it to the heat storage device. Related to the typical requirements of a grid operator, CSP plants can be considered similar to any conventional fuel-fired power station, but with less or no fuel consumption. Therefore, CSP plants represent important elements for maintaining grid stability and control in future electricity supply systems based mainly on renewable energy sources. CSP plants can have capacities from 5 to several 100 MW of electricity generation (Trieb et al. 2009).

One of the benefits of CSP power plants is the fact that the steam turbines usually used for power generation provide an excellent spinning reserve: Such a reserve is very important for short-time compensation of any failures or outages within the electricity grid. Spinning reserves can only be provided by rotating generators such as steam or gas turbines. Moreover, the flexible design of CSP plants allows them to operate in all load segments from base-load and intermediate-load to peak-load services, just as often required by grid operators (Trieb et al. 2009).

A major advantage of the CSP technology is illustrated in **Figure 9**. The figure illustrates a simulated time series of one week of operation of equivalent wind, PV, and CSP systems with 10 MW installed power capacity each at Hurghada, Egypt. As can be seen, whereas wind and photovoltaic power systems deliver fluctuating power and either allow only for intermittent solar operation or require considerable conventional backup, a concentrating solar power plant can deliver stable and constant power capacity because of its thermal energy storage capability and to the possibility of hybrid operation with fuel (Trieb et al. 2009).

To cover a constant load or to follow a changing load by wind or PV electricity would additionally require the electricity grid and conventional plants for external backup. In both cases, an additional backup capacity would have to be installed and operated for most of the time, generating a relatively small portion of electricity during daytime and wind periods, but full capacity during night and periods without significant wind. In our example, the renewable share provided by CSP is about 90%, that of PV is 25%, and that of wind power is about 35–40%. Depending on varying conditions at different locations, these numbers also can be considered as typical for the average annual renewable share of such systems (Trieb et al. 2009).

As a consequence, CSP plants can save more fossil fuel and replace more conventional power capacity compared with other renewable energy sources such as PV and wind power. Theoretically, instead of conventional backup power or fuel, electricity generated by all three systems could be stored in batteries, pump storage, or hydrogen energy storage in order to

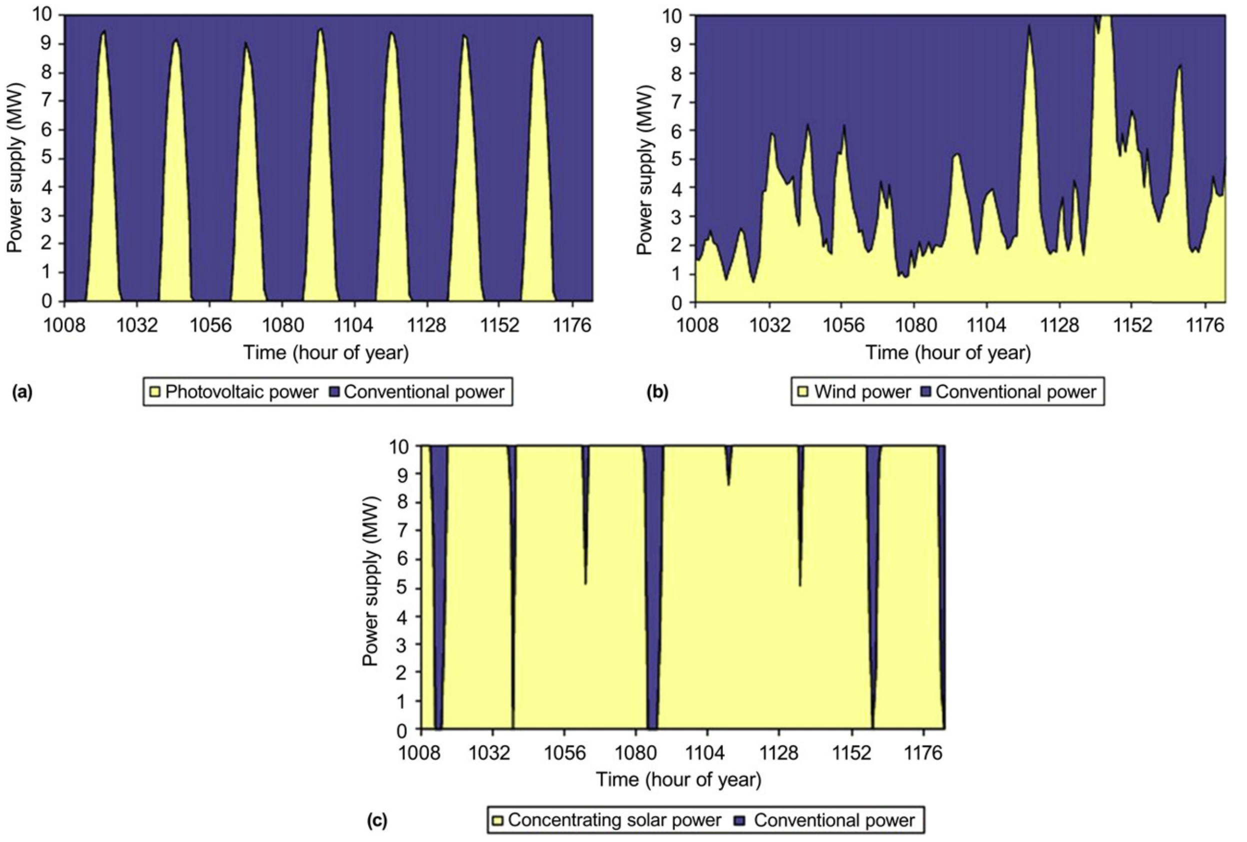

Figure 9 Power supplied by 10 MW capacity (**a**) PV, (**b**) wind, and (**c**) CSP plant (all in yellow) and conventional backup power from the grid (in blue) needed to provide constant 10 MW base load supply, simulated for solar irradiation and wind conditions in Hurghada, Egypt. Source: Trieb, F., and Coauthors, 2009: *Combined Solar Power and Desalination Plants: Techno-Economic Potential in Mediterranean Partner Countries – WP1: Technology Review and Selection of CSP and Desalination Configurations adapted for Application in the Southern and Eastern Mediterranean Region; Final Report*, 117 pp.

provide continuous power capacity. In that case, the additional electrical storage capacities needed by CSP would be rather small, whereas significant storage would be required for PV and wind power, prohibitively increasing the overall system cost and energy losses (Trieb et al. 2009).

A reasonable economic performance of concentrating solar power plants is reached at an annual direct solar irradiance of more than 2000 kWh m^{-2} $year^{-1}$. The economic potential of CSP in Europe has been assessed in Trieb et al. (2005). It is limited to Spain, Portugal, Greece, Turkey, and the Mediterranean Islands and amounts to 1580 TWh $year^{-1}$, of which 1280 TWh $year^{-1}$ are located in southern Spain. Although there is a relatively large CSP potential in Europe, more attractive sites are located south of the Mediterranean Sea with an annual direct solar irradiance of up to 2800 kWh m^{-2} $year^{-1}$.

For concentration of the incoming sunlight, most systems use curved or flat glass mirrors because of their very high reflectivity. Point focusing and line focusing collector systems are used, as shown in Figure 10. These systems can only use the direct portion of solar radiation, but not its diffuse component, which cannot be concentrated by mirrors. Line focusing systems are easier to handle than point concentrating systems, but have a lower concentration factor and hence achieve lower temperatures than point focusing systems. Therefore, line concentrating systems will typically be connected to steam cycle power stations, whereas point concentrating systems are additionally capable of driving gas turbines or combustion engines (Trieb et al. 2009).

More details to these and additional CSP technologies can be found in Trieb et al. (2009). In the following, I will briefly describe the three technologies depicted in Figure 10 in more detail.

3.11.5.2 Brief Review of Major Types of CSP Technologies (This section is largely based on Trieb et al. (2009))

3.11.5.2.1 Parabolic Trough Collectors for Steam Cycle Power Plants

3.11.5.2.1.1 Parabolic Trough Collector with Synthetic Heat Transfer Fluid Some line focusing systems use parabolic trough mirrors and specially coated steel absorber tubes to convert sunlight into useful heat (cf. Figure 10). The troughs are normally designed to track the sun along one axis, predominantly north–south. To generate electricity, a fluid flowing through the absorber tube – usually synthetic oil or water/steam – transfers the heat to a conventional steam turbine power cycle. Concentrating the sunlight by about 70–100 times, typical operating temperatures are in the range of 350–550 °C. Plants of 200 MW rated power and more can be built with this technology.

In order to increase the number of solar operating hours beyond the times when the sun shines, the collector field can be designed to provide, under standard conditions, more energy than the turbine can accept. This surplus energy is used to charge a heat storage medium, which can provide the required energy input to the turbine system during periods of insufficient solar radiation (see below).

The experience of parabolic trough steam cycles dates back to 1985, when the first of a series of nine solar electricity generating systems (SEGS) was commissioned in California, with a rated capacity between 14 MW (SEGS I) and 80 MW (SEGS IX, commissioned in 1991). The plants have been run

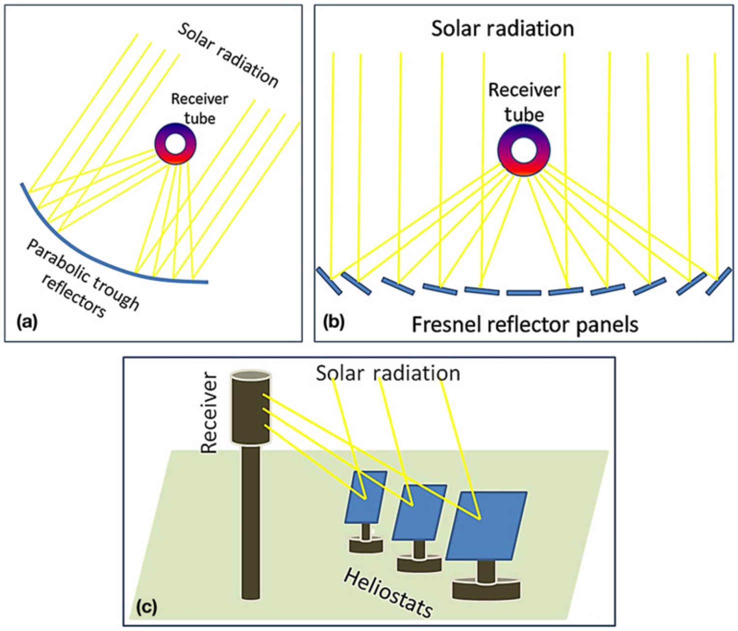

Figure 10 Major elements and principles of the three principle CSP technologies: (**a**) Parabolic trough technology, (**b**) linear Fresnel technology, and (**c**) point concentrator technology (dish-Stirling engines are not shown here).

successfully since then, producing more than 15 000 GWh of solar electricity up to now (for more details, see Trieb et al. 2009, 2005).

3.11.5.2.1.2 Parabolic Trough for Direct Steam Generation

The present parabolic trough plant design uses a synthetic oil to transfer energy to the steam generator of the power plant cycle. Direct solar steam generation in the absorber tubes of parabolic trough collectors is a promising option for improving the economy of solar thermal power plants (Eck and Steinmann 2005), because all oil-related components become obsolete and steam temperature (and hence efficiency) can be increased. First tests have demonstrated the technical feasibility of this technology (Trieb et al. 2009).

3.11.5.2.2 Linear Fresnel Collectors for Steam Cycle Power Plants

Instead of singular parabolic troughs, newer developments have employed a number of horizontal reflector elements that can be controlled individually (cf. Figure 10); they have been labeled linear Fresnel systems. In a Fresnel system, the parabolic shape of the trough is split into several smaller, relatively flat segments. These are put on a horizontal rack and connected at different angles to a rod-bar that moves them simultaneously to track the sun during the day. Because of this arrangement, the absorber tube can be fixed above the mirrors in the center of the solar field, and does not have to be moved together with the mirror during sun tracking.

Such linear Fresnel systems have recently been developed in order to employ a simpler design at lower cost than the parabolic trough technology; for example, linear Fresnel collector systems show a weight reduction per unit area of about 75% relative to parabolic troughs. On the other hand, the simple optical design of the Fresnel system leads to a lower optical efficiency of the collector field, requiring about 33–38% more mirror aperture area for the same solar energy yield compared with the parabolic trough. First prototypes realized up to now show promising results, and first power plants are presently in the design phase.

With regard to the environmental impacts of a given solar field, Fresnel systems have considerable advantages over parabolic troughs. Land use requirements are much lower, as the distances between mirrors are much smaller. The collector aperture area covers between 65 and 90% of the required land, whereas for a parabolic trough, only 33% of the land is covered by mirrors, because the distances between the single parabolic-trough-rows required to avoid mutual shading are considerable. Considering the lower optical efficiency of the Fresnel system (i.e., about 66% of that of a parabolic trough system), linear Fresnel systems attain a solar energy yield per square meter of land about twice that of a parabolic trough system.

3.11.5.2.3 Central Receiver Systems for Steam Cycle Power Plants

The most common form of central receiver system is solar power towers. They consist of an array of dual-axis tracking reflectors (heliostats) that concentrate light on a central receiver at the top of a tower where it usually raises the temperature of a heat transfer fluid (water or oil) to significant temperatures of between 500 and 1000 °C. This fluid is subsequently used as a heat source for a power generation or energy storage system.

Heliostats are devices that consist of one or more mirrors, usually plane ones, which can be individually controlled and moved in order to keep reflecting sunlight directed toward the central receiver, thus compensating for the sun's apparent motions in the sky. In almost every case, the target is stationary relative to the heliostat, so the light is reflected in a fixed direction.

Despite the fact that power-tower developments are somewhat less mature compared with parabolic trough systems, they offer higher efficiency and better energy storage capability. As of now, an increasing number of experimental but also commercial systems have been erected. The Solar Two in Dagget, California, USA, and the Planta Solar 10 (PS10) in Sanlucar la Mayor, Spain, are representative examples of this technology.

The PS10 is comprised of 624 heliostats; each one with a mobile 120 m^2 curved reflective surface mirror. The receiver is designed to produce saturated steam at 250 °C from thermal energy supplied by concentrated solar radiation. The thermal power received by the receiver is about 55 MW at full load. The system has a saturated water thermal storage with a capacity of 20 MWh. A part of the steam produced is used to load the thermal storage system during the full load operation of the plant.

3.11.5.3 Heat-Storage Technologies

3.11.5.3.1 Principles of Heat Storage

The option of heat storage is one of the most distinguishing features of CSP power plants in comparison with other renewable energy technologies such as wind power or photovoltaics. It allows the generation of electricity on demand similar to plants driven by fuel oil or natural gas, despite the fact that CSP plants are based on fluctuating solar energy resources. This represents a very important option that allows increasing the revenues from power sales, because off-peak solar energy from the morning hours can be shifted to the evening on-peak electricity demand, when sales prices may be a factor of two or three higher than in the off-peak hours.

If CSP plants are utilized for seawater desalination, as well (see below), the continuous operation of the desalination plants – either as reverse osmosis plant or through thermal desalination – is crucial in order to avoid scaling and biofouling, which would occur immediately if plants would be left idle.

Employing heat storage in CSP plants has for long been considered a major advantage of this technology and a significant body of experience has been accumulated globally over the last decades (Figure 11). Various technologies and media have been developed and employed in heat storage. The direct storage of heat in synthetic-oil heat transfer fluid (HFT) and molten salt as storage media have been investigated and utilized in the power industry since the 1980s and can thus be considered as fully commercial. However, because the use of HTF as a storage medium is considered too costly, molten salt has been developed to maturity and is currently applied in several CSP plants in Spain.

However, in addition to these well-established technologies, new storage concepts based on concrete and phase-change material are presently under investigation. These, along with

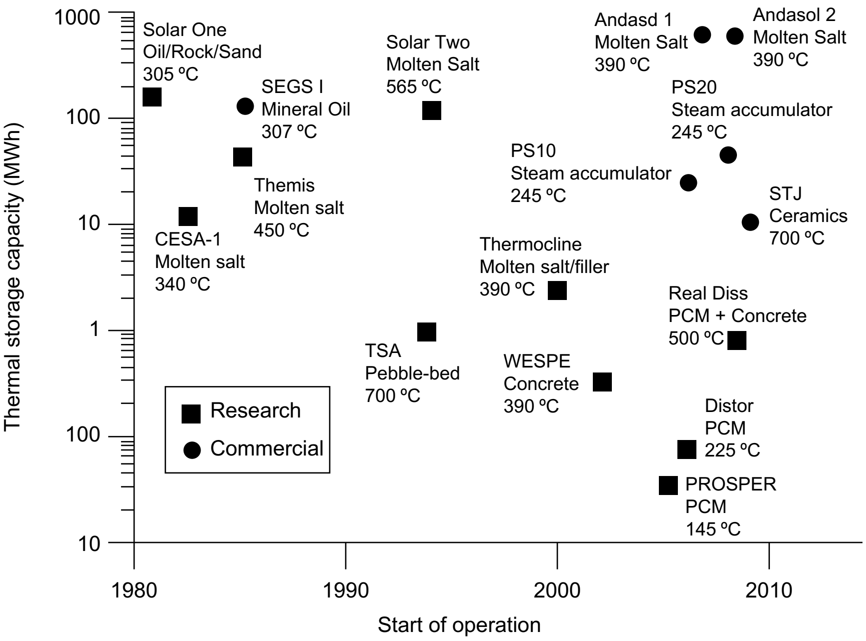

Figure 11 Experiences gained in employing energy storage in CSP plants over the last three decades. Source: Zunft, S., D. Laing, and R. Tamme, 2008: Speicher für Solare Turmkraftwerke, 11. Sonnenkolloquium 2008 "Solare Turmkraftwerke," Cologne, Germany.

the aforementioned established technologies will be described in more detail in the sections that follow.

3.11.5.3.2 Sensible Heat Two-Tank Molten Salt Storage

Molten salt is a medium often used for industrial thermal energy storage. It is relatively cost effective, nonflammable, and nontoxic. The most common molten salt is a binary mixture of 60% sodium nitrate ($NaNO_3$) and 40% potassium nitrate (KNO_3). During operation of the CSP plant, the mixture is maintained at 290 °C in the cold storage tank, and can be heated up to 565 °C. Two-tank storage systems are very efficient, with about 1–2% thermal loss over a one day storage period. Because the molten salt mixture freezes at temperatures at or below about 230 °C (depending on the composition of the salt), care must be taken to prevent it from freezing at night, especially in any of the piping systems. This would lead to irreparable damage to the heat storage installation at the plant and therefore is usually prevented by applying heating by external sources.

Heat exchangers are used to transfer the thermal energy from the heat transfer fluid warmed up by the solar field to the hot tank. During discharge, the heat transfer fluid is circulated through the same heat exchangers to extract the heat from the storage medium and transfer it to the solar steam generator of the power plant. The cost of investment of a two-tank molten salt system amounts to about €40–60 kWh^{-1}.

3.11.5.3.3 Sensible Heat Concrete Storage

A sensible heat storage system using concrete as storage material has been developed by the Ed. Züblin AG and the German Aerospace Center (DLR), Germany. A major motivation for employing this material is the significant cost reduction of the heat exchanger and the high temperatures that concrete storage material can withstand. For live-cycle tests and additional improvements of the original design, a 20 m^3 solid media storage test module was built and thermally cycled through an electrically heated thermal oil loop. The solid media storage test module has successfully accumulated about 1 year of operation in a temperature range between 300 and 400 °C. Investments needed for this technology amount to about €30–40 kWh^{-1} at present prices with a medium term cost target of €20 kWh^{-1}.

3.11.5.3.4 Latent Heat Phase-Change-Material Storage

Latent heat phase-change-material (PCM) storage technologies represent relative recent developments. A major technical challenge for a successful implementation of high-temperature latent heat storage systems is the insufficient thermal conductivity of the available phase-change materials of around 0.5 $W(m\,K)^{-1}$. During the discharge process, the energy released by solidification of the storage material must be transported from the solid–liquid interface through the growing solid layer to the heat exchanger surface, which is slowed down by the low thermal conductivity of the solid PCM.

Enhanced heat exchange has been achieved through the use of fins attached vertically to the heat exchanger tubes within the storage material. Fins can be manufactured of graphite foil, aluminum, or steel. High-temperature latent heat storage technologies with high-capacity factors have been demonstrated at different temperature levels. The sandwich concept using fins made either from graphite or aluminum has proved to be the best option to realize cost-effective latent heat energy storage. The application of graphite is preferred for applications up 250 °C; at higher temperatures aluminum fins are used.

PCM test storage facilities with a capacity of approximately 700 kWh are currently being manufactured. Research activities aim at the thermoeconomic optimization of the storage concept; further storage systems using the sandwich concept are

under development. Investment costs of €40–50 kWh^{-1} are foreseen for large scale storage systems.

3.11.6 CSP for the Cogeneration of Electricity and Desalinated Seawater

3.11.6.1 Basic Concepts

Figure 12 depicts the basic components of an operational CSP-parabolic-trough plant. A CSP plant also can be used to enable the desalination of seawater (DSW). Thus, such an integrated plant would enable the cogeneration of electrical power and desalinated seawater (called here a CSP–DSW plant). This addresses a number of particularly pressing problems in many countries, for example, Cyprus, including:

1. The generation of electricity by renewable sources rather than by the burning of fossil fuels
2. The resultant dependence on fossil fuel and international energy markets if energy is produced conventionally
3. The need for an environmentally friendly production of potable water through desalination

Thus, if realized, substantial benefits may be gained, despite the likely substantial capital investments needed to realize CSP–DSW plant.

The cogeneration of electrical power and desalinated seawater can be accomplished in two ways:

(a) By using the electricity that is being generated in a conventional desalination unit, either RO or MED (or any other desalination technology)
(b) By utilizing the remaining heat of the steam, after it has passed through the steam generator to produce electricity, as entry fluid for the first effect of a MED plant.

Whereas option (a) can be realized with any renewable power source (e.g., photovoltaics or wind), and option (b) is particularly – if not exclusively – suited for a CSP plant. Neither of the options has been realized in any operational plant at the present, even though currently operating CSP plants such as the ANDASOL 1 plant could readily accommodate a desalination unit according to option (a) (Trieb et al. 2009).

3.11.6.2 The CSP–DSW Project

The full integration of option (b) is less readily accomplished, but has been studied in detail by the Energy, Environment and Water Research Center (EEWRC) of The Cyprus Institute (2010). Figure 13 depicts schematically the main components of such a plant. The design envisioned incorporates a number of innovative elements/technologies, including:

1. Energy will be harvested by a field of heliostats on a hilly, south-facing location near the sea.
2. The solar energy will be captured by a central receiver and converted to heat and stored in a salt container of novel design at high temperatures.
3. Steam will be generated from the heat reservoir of the salt container or from an alternative thermal storage concept.
4. Electricity will be produced using a commercially available steam extraction turbine.

5. Desalinated water will be produced using an innovative multiple effect distillation (MED) facility with a thermal vapor compressor, from the heat output of the steam turbine and other heat sources of the system.
6. Alternatively or in addition, desalinated seawater may also be generated by an RO plant principally driven by electricity produced in the power cycle of the combined CSP–DSW plant.

It is obvious that the integration of all major components of this plant represents a tremendous integration/optimization task.

However, the Cyprus Institute study results in the conclusion that the concept of cogeneration of electricity and desalinated seawater using concentrated solar power is sound both from an engineering as well as from an economic and policy point of view. The heliostat–central receiver technology is judged to be the most suitable for a situation typical for a small- to medium-sized island such as Cyprus, wherein large flat areas are rather sparse. If implemented in conjunction with a substantial storage capability a 'base load' facility operating on a 24 h a day, 7 days a week schedule may be feasible. A detailed and sophisticated business model of a pilot plant whose conceptual design has been briefly described here reveals that such a plant, with a minimum electricity capacity of 4 MW_e and a (possibly) hybrid MED/RO desalination unit, will be economically feasible.

Currently, a number of detailed studies on key components, (such as the heliostats) as well as the receiver and storage units are currently undertaken at the EEWRC.

3.11.7 Conclusions

This chapter considers the links between water supply and renewable energies. While water scarcity represents a challenge to numerous regions of the world at present, climatic conditions could exacerbate this problem. In addition, groundwater resources in many parts of the world are increasingly threatened by overexploitation and/or contamination, implying significant risks to water security.

The provision of potable water in sufficient quantities and adequate quality in these regions is closely linked with energy needs, particularly, when seawater desalination is employed as a major source of drinking water. Renewable energies, notably solar energy, represent a viable alternative to conventional energy sources. This is particularly relevant for Northern Africa as well as countries of the eastern Mediterranean, as these regions combine significant water scarcity (cf. Figure 4) with copious quantities of solar irradiation (cf. Figure 3).

Novel technologies employing concentrating solar power for the cogeneration of electricity and desalinated seawater (CSP–DSW plants) have been addressed in recent studies (see, e.g., The Cyprus Institute 2010; Trieb et al. 2009). Such plants will have the advantage of addressing various particularly pressing problems in many countries, for example, Cyprus: (1) the generation of electricity by renewable sources rather than by the burning of fossil fuels, (2) the resultant dependence on fossil fuel and international energy markets if energy is produced conventionally, and (3) the need for environmentally friendly production of potable water through desalination. Thus, if realized, substantial benefits may be gained, despite the likely substantial capital investments needed to realize CSP–DSW plant. Although the overall technical and economical feasibility of a CSP–DSW plant has been demonstrated (The Cyprus Institute 2010), studies undertaken at present address a number of technical issues that need further clarification.

Glossary

Air changes per hour (ACH) The fraction of a building's air volume, which is replaced each hour due to infiltration or ventilation use of outside air.

Anthropogenic Heat Sensible heat released to the environment as a result of energy use for human activities (aka waste heat). Examples of anthropogenic heat sources include automobile tailpipes, rooftop air conditioning equipment, and smokestacks associated with industrial processes.

Building envelope The outer shell of a building that separates the indoor and outdoor environments. This envelope consists of foundations, roofs, walls, doors, and windows.

Climate zone A geographical region (contiguous or otherwise) for which one representative set of climate characteristics can be defined for the purpose of building construction/insulation guidelines or standards. For example, the International Energy Conservation Code divides the world's climate into eight such zones.

Cooling and heating degree days Heating degree days (HDD) are calculated by subtracting the actual temperature from a base temperature (often 65 °F or 18 °C). This is done for each hour in a month or year and all nonnegative values are summed to obtain a total number of HDD. The premise is that additional heating is required for every hour when the temperature is below the base temperature and is proportional to the magnitude of this temperature difference. Cooling degree days (CDD) are calculated in the same way, but with the base temperature subtracted from the actual hourly temperature.

Design days In designing buildings it is generally desirable to size mechanical heating and cooling equipment so that they can meet comfort requirements for most days of the year. These sizing calculations are generally performed using a winter design day (typical very cold day) and a summer design day (typical very hot day). These design days do not represent absolute extreme conditions for the location under study. Rather, it is fully expected that there will be a small number of hours in any year when the building's heating and cooling equipment are not sufficient to maintain thermal comfort – for example, the building is slightly warmer or colder than desired.

Energy use intensity (EUI) The ratio of annual site energy use by a building to the floor area of that building. Sometimes EUI is applied just to electrical energy use. Other times it refers to the whole building energy use.

HVAC Energy use for Heating, Ventilation, and Air Conditioning (HVAC) is commonly lumped as a single quantity for analysis and discussion.

Operative temperature The equivalent temperature of an enclosure in which an occupant would experience the same heat gain or loss from radiation and convection as in the occupant's actual environment. This temperature takes into account not only ambient air temperatures and air velocity (for convection), but also the surface temperatures at which the walls, ceiling, and floor are radiating.

http://dx.doi.org/10.1016/B978-0-12-384703-4.00321-X

Peak Load Regional or local energy consumption generally peaks as a result of climate-dependent heating and cooling loads. Peak electric load in the summer is typically associated with high demand for air conditioning in the late afternoon hours. Peak electric load often dictates the generation capacity requirements.

Site/Source energy Site energy is the energy delivered to the building. The concept of source energy attempts to include the inefficiencies associated with power generation and transmission from power plants to the building. The site to source conversion factor used to account for these inefficiencies is typically between 2.5 and 3.5.

Typical meteorological year (TMY) A TMY is a representative description of the weather that a building might be expected to experience in a particular location, usually based on data from a local airport weather station. It is generally prescribed as a year's worth of hourly values for outdoor weather – temperature, humidity, wind speeds, solar radiation, etc. The TMY is distinct from the concept of a climate average in that it is generally comprised of actual data from the historical record, aggregated at the monthly level and smoothed. As such, it retains multiday weather events such as heat waves and droughts. For example, a TMY file for a particular site might include the weather from January of 2001, February of 2005, March of 1999, and so forth.

3.12.1 Introduction

Energy is central to the success of modern societies representing a fundamental resource, as well as a constraint for urban development. As cities grow, so too does the demand for energy and the various environmental consequences associated with energy production, transmission, and consumption. The global population continues to urbanize with the balance shifting from a primarily rural world to an urban one, just in the last 5 years. In larger industrialized nations such as the United States, upward of 75% of the population now lives and works in or near cities, and the average urban dweller spends on the order of 80% of their daily life in buildings. Buildings provide multiple functions in modern society. At a fundamental level, they provide shelter from the outdoor weather. This includes shelter from precipitation, winds, and undesirably hot or cold air temperatures. Buildings also provide the infrastructure for accomplishing work and entertainment. Electricity transmission lines and natural gas pipes supply the energy needed to power lighting, heating and cooling equipment, computers, televisions, and a myriad of office and household appliances. It therefore comes as no surprise that buildings represent the single largest consumer of energy in most developed nations. For example, in the United States it is estimated that buildings represent about 40% of all energy use with the remainder being roughly evenly split among the transportation and industry sectors. Of the sources of energy for end-use applications in buildings, electricity is the most versatile, and hence represents on the order of 70% of all energy use in buildings. Natural gas, fuel oil, and other types of heating fuels represent the remaining 30%.

In evaluating the relative energy efficiency of buildings, it is important to consider building use and climate. One useful metric of energy use in buildings is the Energy Use Intensity (EUI). The EUI is typically defined as the ratio of annual site energy use to building floor area. It can be used to refer just to the electricity use in a building – in which case it is usually defined in units of kBTU ft^{-2} or kWh m^{-2}. For example, the U.S. Department of Energy indicates that for new construction the EUI ranges from about 40 to 68 kBTU ft^{-2} (120–200 kWh m^{-2}) for large office buildings depending upon climate. The highest EUI values are associated with the coldest climates (e.g., Fairbanks, Alaska). The least energy intensive buildings are warehouses, and the most energy intensive buildings are generally restaurants and fast food establishments. Based on data from the Commercial Building Energy Consumption Survey (CBECS) across the United States, existing office building stock has an EUI in the range of 80–100 kBTU ft^{-2} (240–300 kWh m^{-2}), depending upon size category. In contrast, hospitals, restaurants, fast food, and supermarkets all have EUIs greater than 200 kBTU ft^{-2} (600 kWh m^{-2}).

The energy sector – and energy use in buildings, in particular – is inextricably linked with the urban climate system. Energy generation and consumption both affect and are affected by the urban climate in many complex ways. Perhaps the best known connection between energy and climate is the relationship between fossil fuel combustion in power plants and the release of carbon dioxide into the atmosphere. This emission of CO_2 is one of the major drivers of anthropogenic changes in climate statistics at the global scale (NRC 2005). Of course, fossil fuel combustion results in many other atmospheric emissions that contribute to both global and local environmental challenges. These emissions include particulate matter, such as fly ash and secondary sulfates and nitrates from coal-fired plants. The size distribution and chemical composition of particulate emissions from power plants determine their relative impacts on human health. Other emissions from fossil fuel plants include heat, water vapor, carbon monoxide, non-methane organic compounds, mercury, and various radioactive trace elements (particularly from coal combustion). These emissions have atmospheric residence times that range from minutes or days (e.g., water vapor) to tens or hundreds of years (e.g., CO_2). As a result, there are both local and global ramifications of power production. Thus, for some emissions from power plants, the relative proximity to population centers and the prevailing wind directions can be important factors in determining direct effects of power plant energy production on the urban atmospheric environment. While some types of power plants (e.g., hydroelectric, solar thermal, and nuclear) have relatively modest atmospheric emissions of chemical pollutants they still emit vast amounts of waste heat and require extensive cooling. Power plant efficiencies, in general, are bounded by Carnot cycle performance constraints, which dictate that the thermal efficiency of a device operating in a cycle between two temperature extremes, T_h and T_c is given by

$$\eta_{\text{th}} \leq 1 - \frac{T_c}{T_h} \qquad [1]$$

Thus, as a result of typical ranges of T_c and T_h available for practical power plant operation ($T_c \sim 300$ K and $T_h \sim 500$–800 K), most power plants operate at thermal efficiencies in the range of 40–60%. Other system inefficiencies such as inability to fully extract chemical energy from the power plant's fuel source further reduce the total power plant efficiency to a typical range of 30–40%. Depending upon the power plant, the waste heat is transferred to the atmospheric environment through evaporation of water in cooling towers, or to a large body of water in the form of a sensible increase in the temperature of the water leaving the cooling system. There are further losses in the transmission of power from power plants to the end users. These losses can be on the order of 0.25–1.0% per km. Thus, there is pressure to locate power plants near major urban centers and industrial consumers. As of 2007, the system-wide transmission and distribution losses in the U.S. electric grid were estimated at 6.5% (EIA 2011).

For every kilowatt hour of electricity delivered to an end user – say to power a desktop computer in an office during a workday – on the order of 2.5–3.0 kWh of fuel energy was expended at the power plant. Even so, that last kWh of energy follows the First Law of Thermodynamics – it is conserved. In the case of the vast majority of energy use in buildings, this conservation takes place in the conversion of energy to low grade waste heat. So, that 1 kWh used to power an office computer ultimately finds its way into the urban atmospheric environment, first by heating up the air in the office and then by being extracted by the building ventilation system.

As will be elaborated on in the following section, energy consumption consists of both a base load component and a weather-sensitive component. There are multiple factors affecting each component and finding levers to manipulate end-use energy consumption has been an ongoing challenge since the oil crisis of the 1970s. Base loads depend on technological innovation and human behavior, as well as their interactions. An interesting example of technological innovation at odds with human behavior is the evolution in refrigerator efficiencies that took place over several decades in the United States. In 1970, the average refrigerator used about 100 kWh year^{-1} of energy for each cubic foot of capacity. By the year 2000, through implementation of various standards – largely driven by California Energy Commission efforts – this average was reduced by more than a factor of three to about 30 kWh year^{-1} for each cubic foot of capacity. This was a great triumph on the technology side, driven by regulation. At the same time, however, technological progress led to a significant reduction in unit costs for refrigerators, from $1000 in 1970 to less than $500 in 2000. As a result, average refrigerator capacity increased by about 20% during this same period. Also, while it was quite uncommon in the 1970s for a household to have more than one refrigerator, it is much more common in modern U.S. households (EIA 2005). So, the tremendous energy savings made possible by efficiency improvements were somewhat reduced by evolving social and economic factors.

The portion of building energy consumption that depends strongly on weather is referred to as the weather-sensitive load. This load consists of air conditioning in summer, and heating in winter. Clearly, the relative magnitudes of heating and cooling demand are a strong function of climate. In some climates there is very little demand for heating, while in others there is little demand for cooling. There is a third class of cities, which have a more balanced demand for heating and cooling. As a result, building codes and practices vary substantially as a function of geographical location. Of course, weather-sensitive loads also depend very much on human behavior. There are well-established relationships between air conditioning energy consumption and outside air temperature. Multiple researchers, for example, have published data suggesting that in many U.S. cities total summer electricity use increases by 3–5 % per degree centigrade increase in the outdoor air temperature (Akbari et al. 1999; Akbari and Konopacki 2005; Lu et al. 2009). This sensitivity has important implications as it relates to both regional scale climate and local urban heat island (UHI) intensification. There are also data, however, suggesting that air conditioning behavior evolves. For example, in 1995 only about 33% of single family homes in Portland Oregon – a relatively mild summer climate – had air conditioning systems (AHS 1997). This number has grown at a rapid pace in recent years, increasing to 44% in 2002, and an estimated 50% or higher currently. This compares with more than 90% of residences across the entire United States that have some form of air conditioning (AHS 2009). This evolution likely is a result of relative costs for air conditioning equipment as well as an influx of residents from climates where air conditioning is prevalent, and the notion of buying a house without an air conditioner seems strange. This example points out a potential vulnerability that might be found in certain climate regions. Namely, as the local climate warms there may be a nonlinear increase in energy use for air conditioning due to the combined factors of increased market saturation of air conditioning and the underlying sensitivity of air conditioning energy use to ambient air temperatures.

3.12.2 Components of Building Energy Consumption

Energy consumption in buildings is as diverse as the many types of buildings and the climates within which they reside. Nevertheless, the end uses for which energy is consumed in buildings can be organized into four categories: lighting, plug loads, HVAC loads, and miscellaneous equipment. Each of these categories, in turn, consists of subcomponents, the relative magnitude of which will vary across the population of buildings. Energy use in each category also varies seasonally and diurnally due to variations in both weather and occupancy. While the role of weather is explicitly discussed in Section 3.12.3 Factors Influencing Building Energy Use, it is important to consider occupancy prior to discussing the specific components of energy use. So, the subsections below provide an overview of occupancy, followed by detailed descriptions of energy use within each end-use category. The last two subsections then describe variations in these loads as a function of building type residential–commercial.

3.12.2.1 Occupancy

Buildings exist to provide occupants with shelter from the outdoor environment and to create conditions suitable for everyday activities. So, one would expect that energy use in buildings ought to scale to some extent with the occupant density. An office building, for example, that opens early in the morning and closes in the evening should have relatively little energy consumption during the night. In contrast, an apartment whose occupant works during the day should have relatively little energy consumption during the day. So, in analyzing energy use in buildings it is important first to gain an understanding of occupancy. Of course, the scaling of energy use with occupancy is far from linear and differs for each subcomponent of energy consumption described below. Consider for example increasing occupancy from one to two persons per office. The lighting requirements for the space may only increase a small amount if at all, whereas the ventilation requirements and energy use for computing equipment essentially doubles.

Occupancy is often described using a 'design' value and a schedule. The design value is an estimate of the total space per occupant when the building is fully occupied. In models which simulate energy consumption in buildings, this is often given in terms of floor space per person. Common values range from 15 to 20 m^2 per person for an office space to 2–4 m^2 per person for a conference room. In computer modeling of building performance, it is generally assumed that for a commercial building the occupancy has a workday schedule that peaks around 80–90% of capacity in the early morning and mid-afternoon hours, with distinctive ramps from-to zero occupancy in the early morning and evening hours, and a lunchtime reduction in occupancy to around 50% of capacity (c.f., Hirsch 2011). Occupancy in residential buildings is typically much lower than that for commercial buildings. For example, a single occupant apartment is typically larger than 40 m^2, and a detached home for a family of four is usually larger than 180 m^2 ($\sim$1900 ft^2) or 45 m^2 per person. Aside from the end-use energy consumed by each occupant while in the building, occupants themselves act as sources of heat and moisture through metabolism and respiration processes. In fact, the typical person has a daily caloric intake that results in an average metabolic heat release of about 75–100 W.

3.12.2.2 Lighting

Lighting is an essential need in modern buildings. It enables extension of indoor activities well beyond sunset and ensures security and safety around perimeters of buildings, as well as in interior spaces such as stairwells. It is therefore a significant component of the total energy consumption in a building, often comprising 20–30% of total building energy consumption. Lighting needs are generally reported in terms of power per unit area ($W\,m^{-2}$), and lighting levels differ depending upon the intended use of a space. For example, typical lighting power for offices, hallways, and conference rooms is 14, 6, and 17 $W\,m^{-2}$, respectively. As with occupancy, these are the values assumed for full occupancy. With the exception of emergency and safety lighting, the actual lighting level in a building varies over the course of a day. It may peak around 90% of installed capacity and is generally no more than 5% of these peak values at night or on nonworking days.

The role of lighting in energy use and climate is twofold. First, the electricity used to power lights has its origin at a power station. So, there are waste heat and pollution emissions at the power plant, as well as losses in the transmission of this electrical energy to the building. Depending upon the technology used for lighting – for example, incandescent, fluorescent, compact fluorescent (CFL), or light emitting diode (LED) – the conversion of electrical energy to light will result in a certain amount of local waste heat at the point of use. As a general rule, to obtain the same level of lighting, incandescent lighting requires three to four times the power of CFL and five to six times the power of LED technology. Any energy used by lighting fixtures that does not generate visible light results in heat at the light bulb or fixture. It is important to note also that much of the light energy eventually gets converted to heat. Specifically, as light illuminates an interior wall it is partially absorbed and partially reflected. So, any light that does not escape through windows is also converted to heat in the building. This is why replacing inefficient incandescent bulbs with LEDs will reduce air conditioning loads in summer, but will also increase heating loads in winter. The same is true for other end-use efficiency measures related to plug loads and miscellaneous equipment.

3.12.2.3 Plug Loads and Miscellaneous Equipment

Plug loads consist of any electrical appliance that is plugged into an outlet. This includes items such as desktop computers, televisions, radios, and space heaters. Plug loads vary quite a bit depending not only upon building design, but also on occupant schedules and personal energy behavior. Thus, it is not uncommon for initial estimates of plug loads in a building to be off by ±25%. Underestimation of plug loads tends to be more common. This contributes to underestimates of air conditioning energy use and overestimates of heating energy use. As a general rule, plug loads are in the range of 10–20 $W\,m^{-2}$ for offices. Plug loads are generally closely tied to occupancy. Of course, many devices continue to draw power even when they appear to be turned off. These loads are generally referred to as phantom loads, but are usually only a few tenths of a watt to several watts per device.

3.12.2.4 HVAC Loads Including Environmental Loads

Most modern buildings require some level of heating, cooling, and mechanical ventilation. The heating and cooling demand is generally driven by the goal of maintaining the occupied space within a comfortable temperature and humidity range. The most widely promoted guidance for thermal comfort comes from the American Society for Heating, Refrigeration and Air Conditioning Engineers (ASHRAE) in the form of the ASHRAE 55 standard for Thermal Environmental Conditions for Human Occupancy (ANSI/ASHRAE 2010). The acceptable range of thermal comfort depends upon temperature and humidity, but also factors in seasonal and clothing considerations.

The extent to which indoor ambient conditions deviate from the comfort region in Figure 1 results in the demand for heating, cooling, or dehumidification. The vertical axis in this figure is the

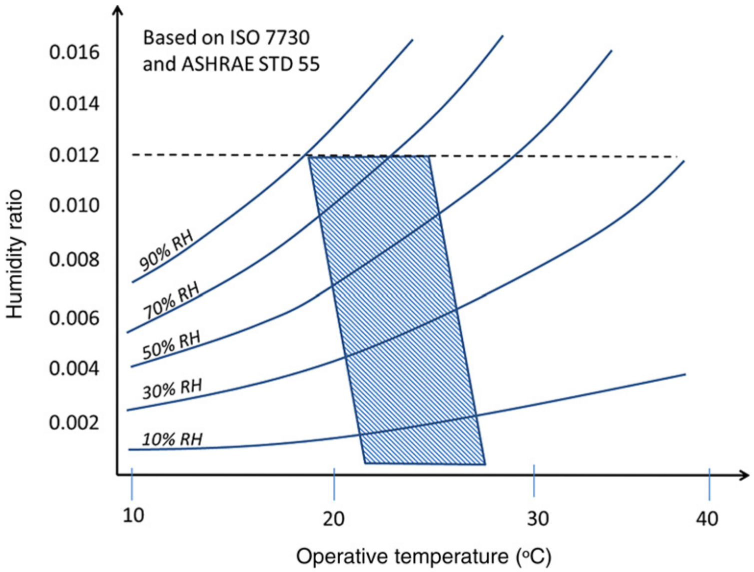

Figure 1 Thermal comfort diagram (after ASHRAE 55 standard). Shaded region represents temperature and humidity range within which typical building occupants are comfortable. Actual location and size of this region shifts as a function of clothing level and individual preferences. Reproduced from ANSI/ASHRAE, 2010: *Standard 55-2010–Thermal Environmental Conditions for Human Occupancy* (ANSI approved). ASHRAE, 40.

nondimensional humidity ratio – mass of moisture in a unit volume of air divided by the mass of the dry air volume. The horizontal axis is the operative temperature which is a measure of the effective temperature that a person is exposed to – accounting for sensible air temperature, as well as radiant and convective exchange with the surroundings. The shaded region in this figure represents a region of conditions within which a typical person would feel comfortable. This figure illustrates the importance of both temperature and humidity in affecting thermal comfort. Often, the cooling equipment in a building act as the mechanism for dehumidification – for example, residences in the southern United States often run their air conditioners throughout the night during hot and humid summer months in order to remove moisture from the indoor air, even though the air temperature might otherwise be comfortable.

In the absence of mechanical HVAC systems indoor conditions will vary in response to multiple factors. First, internal loads (plug and lighting loads and various electric and gas powered appliances) within the building necessarily result in waste heat. This waste heat warms the indoor air and the interior surface temperatures. As a general rule of thumb, every joules of energy consumed within the building results in a joule of waste heat within the building. The exceptions include the direct loss of lighting power through windows and the removal of heated water through sewer pipes. As a direct function of human (and pet) metabolism, occupants within a building are another source of heat. As noted earlier, this metabolic heat loss varies from individual to individual and as a function of activities, but in general, each human occupant represents an additional 75–100 W of heating. These internal loads associated with energy use and occupancy, however, are sometimes exceeded by external loads associated with the outdoor environment.

Solar radiation is one of the most significant external loads on a building, particularly in the summer season. Depending upon latitude the peak solar radiant flux incident on a building may be as high as $1100\,\mathrm{W\,m^{-2}}$ in summer. This short-wave radiative load on the building penetrates the building envelope through two pathways. Some of the radiation passes directly through the windows. Depending upon the construction details of the windows (e.g., number and thickness of panes of glass, presence of coatings, air gap between panes and frame characteristics) the amount of solar radiation making it through each window may vary from as little as 0.25 for a good double pane window with a reflective coating to as much as 0.85 for a single glazed window. Windows are typically the largest driver of environmental heat gain in buildings. This is due both to the relative transmissivity of windows to solar radiation and the generally high window to wall surface area ratios (windows are generally 30–50% of the wall surface area).

Solar radiation combines with convection to influence the total heat conduction through the opaque surfaces of the building envelope. While this component of environmental load on buildings is typically less significant than the direct solar gain through windows, it can be important depending upon the level of building insulation and the quality and relative surface area of windows.

A final element of environmental loads that is sometimes overlooked is heat and moisture transport across the envelope directly through air exchange. While some level of outdoor air exchange is highly desirable to maintain good air quality, air leakage across the building envelope is generally greater than needed to maintain good air quality. This is particularly true in residential structures where a typical infiltration rate might be on the order of 1–3 air changes per hour (ACH). In the best sealed envelopes the infiltration ACH can still be greater than 0.2. All of this unintentional air exchange between the indoor and outdoor environments leads to movement of heat and moisture across the building envelope.

There is a wide variety of systems in use for heating, cooling, and ventilating buildings. Boilers, furnaces, and electric resistance heaters are typically used to add heat to buildings while cooling is typically accomplished via packaged 'DX' (Direct Expansion) air conditioning units, heat pumps, or cooling towers. Boilers, furnaces, and electrical resistance heaters generally have very high conversion rates – for example, 1.0 J of energy delivered to the building (e.g., via natural gas line or electricity) for heating is converted into very nearly 1.0 J of heat within the building. Some losses exit the building via stacks or chimneys. Ultimately if a building is operating in a nominally steady mode, then all heat added to the building to maintain comfort must be balanced by an equal amount of heat escaping into the urban environment. So, if one knows the quantity of energy used for heating that can be equated directly to anthropogenic waste heat.

Air conditioning is a different story. Different metrics of efficiency apply to the differing types of equipment in use for air conditioning. For example, air conditioning equipment that operates on a refrigeration cycle is generally evaluated based on its Seasonal Energy Efficiency Ratings (SEER) or Coefficient of Performance for a refrigeration cycle ($\mathrm{COP_R}$), where by definition $\mathrm{SEER} = 3.412 * \mathrm{COP_R}$. The coefficient of performance simply measures the desired output of the AC system – the removal of a quantity of heat Q_L from the 'low' or cool side of the cycle (the building) relative to the net amount of work required to accomplish this heat removal process ($W_{\mathrm{net,in}}$):

$$\mathrm{COP_R} = \frac{Q_L}{W_{\mathrm{net,in}}} \qquad [2]$$

But the First Law of Thermodynamics requires that the refrigeration cycle exhausts heat (Q_H) on the hot side of the cycle (the outdoor environment) with the resulting energy balance:

$$Q_H = Q_L + W_{\mathrm{net,in}} \qquad [3]$$

Combining these expressions,

$$Q_H = W_{\mathrm{net,in}}(1 + \mathrm{COP}) \qquad [4]$$

Thus, the amount of heat exhausted into the outdoor environment (Q_H) by a traditional refrigeration cycle-based air conditioning system will be larger than the amount of heat removed from the building. In fact, $\mathrm{COP_R}$ values generally range from about 2 for older systems to more than 4 for some of the newer technologies. This means that for every joule of energy used to cool a building ($W_{\mathrm{net,in}} = 1\,\mathrm{J}$) the waste heat removed from a building ($Q_H = 3\text{–}5\,\mathrm{J}$). So, in estimating the anthropogenic waste heat associated with DX-style air conditioners it is important to note that the waste heat is at least three times the magnitude of the energy used for air conditioning. There is an entire class of air conditioning systems, however, for which this analysis is not applicable. Specifically, evaporative–cooling systems, common on larger commercial buildings and also on residential buildings (as 'swamp coolers') in some climates, remove the heat load from the building through a combination of evaporative (latent) and convective (sensible) heat exchange. The actual fraction of building load which is removed in the form of latent heat depends on atmospheric conditions, supply water temperatures, and system operating conditions. So, while it is difficult to predict what fraction of cooling tower waste heat emissions are in the form of latent heat-sensible, such systems often operate with more than half of the waste heat being latent. So, again, energy used to run such systems is not indicative of the amount of sensible waste heat emitted into the urban environment.

So, in summary, there are many factors that contribute to the demand for heating and cooling in a building. Ultimately, the total waste heat emitted from a building is a combination of the heat associated directly with energy use within the building and with the environmental load that would generate energy demand for heating and cooling even in the absence of any energy consumption for other purposes in the building. These factors contributing to waste heat emissions from buildings are summarized in Figure 2.

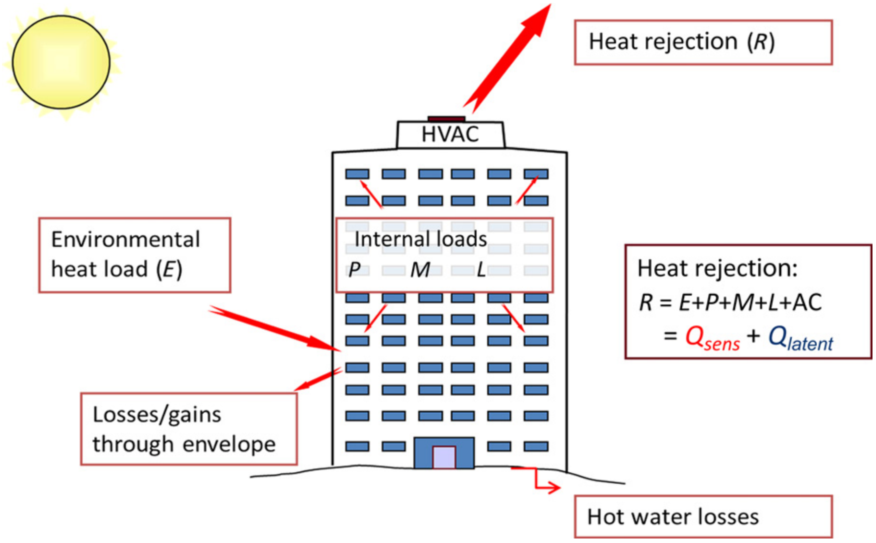

Figure 2 Summary of loads affecting the energy consumption and waste heat emissions from a building. The total heat rejection to the environment is a combination of sensible and latent heat depending upon the type of cooling equipment employed. In summer the environmental loads may be the same order of magnitude as the building energy consumption.

3.12.2.5 Residential Buildings

Residential buildings are broadly classified into multifamily residential (MFR) and single family residential (SFR). These correspond to apartments–condominiums and detached houses. The relative proportion of housing in either of these categories varies widely. In the United States roughly 75% of households are SFR. There can be sharp contrasts from one city-state to another, however. For example, only 51% of the households in the State of New York are SFR. In Midwestern states such as Iowa this fraction increases to 82%.

Variation of energy use across building types can be viewed using two different metrics: energy use per capita and energy use per unit floor area. Densification of the urban population into MFR housing results in a decrease in energy use per capita due to sharing of common energy sources for lighting and HVAC. On the other hand, MFR housing results in an intensification of energy use per unit floor space. Thus, to the extent that MFR housing results in denser populations in cities it also increases the density of energy use and waste heat emissions within the city.

One important characteristic of residential housing is its diurnal and seasonal profiles of energy consumption – and thus waste heat emissions. The typical household is characterized by high levels of activity during the morning and evening hours, with a general reduction in energy use during working hours. The energy consumed for HVAC follows the activity patterns with residential air conditioning driving much of the late summer afternoon (3–5 p.m. local time) peak in many utility load curves. Likewise, the requirement to maintain thermal comfort during cold winter nights results in high levels of heating fuel use throughout winter nights, even though other components of energy use are small.

3.12.2.6 Commercial Buildings

The U.S. Department of Energy's CBECS (EIA 2003) classifies commercial buildings into 14 principal activity categories. The five most prevalent building types (based on total floor space) are: (1) office, (2) mercantile, (3) warehouse storage, (4) education, and (5) lodging. Ranking the same 14 principal activity categories by total primary energy consumption, the five most energy intensive types are: (1) office, (2) education, (3) health care, (4) lodging, and (5) warehouse storage. So, clearly, office buildings are particularly important contributors to the overall building energy consumption in the United States and most industrialized countries. In fact, office buildings in the United States consume 38% more energy than the next most energy intensive building category – education.

In contrast to residential buildings, commercial buildings have energy consumption profiles that are driven largely by the defined work week. That is, most commercial office buildings have very low occupancies on weekends, holidays, and before 7 a.m. and after 6 p.m. local time on a weekday.

Most commercial office buildings are managed in such a way to reduce energy consumption when workers are largely absent. To accomplish this, the ventilation schedule is generally reduced during nonworking hours and the setpoint temperature for thermal control (heating or cooling) is relaxed so that the building's thermal environment is allowed to 'float' at night and on nonwork days. Due to the lag between programmed setpoints and realized thermal comfort in buildings, most commercial office buildings are 'turned on' an hour or so before the first wave of occupants arrive each workday.

3.12.3 Factors Influencing Building Energy Use

Having described the individual components of energy use in buildings, and the roles of occupancy and building class we can now consider the main drivers that influence building energy use with a particular emphasis on the role of climate and weather.

3.12.3.1 Climate and Weather

This section introduces aspects of the urban climate system including regional climate, UHI, and global environmental change with respect to their consequences for energy use in buildings and the associated feedback of waste heat emissions. It answers questions such as: what is the climate-sensitivity of building energy use? It also introduces the concept of positive and negative feedbacks in the system (e.g., global/local warming increases demand for air conditioning in summer and increased AC use results in additional waste heat that further warms urban areas).

The primary connection between outdoor atmospheric conditions and energy use in buildings is the role that ambient temperature plays in affecting heating and cooling loads. A generalized depiction of this relationship for power utilities in hypothetical cities is illustrated in Figure 3. Representative curves are presented for winter peaking (cold climate) and summer peaking (warm climate) utilities. The cooling and heating load sensitivities, S_{CL} and S_{HL}, respectively, indicate the

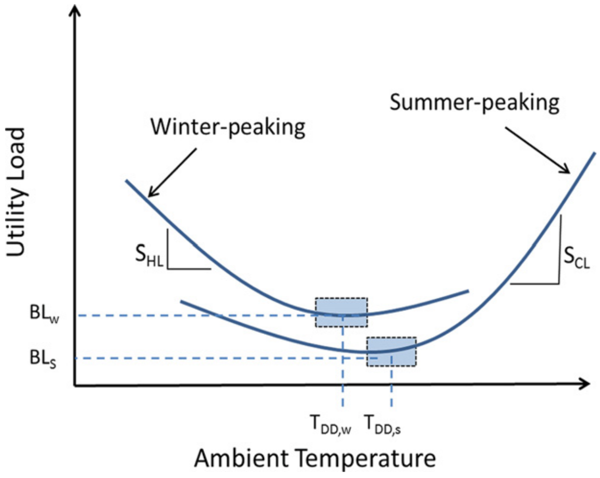

Figure 3 Energy consumption profile as a function of outdoor ambient air temperature. Curves are shown for winter and summer-peaking (cold and warm climate) utilities. Base loads (BL), threshold (T_{DD}) temperatures, and heating and cooling load sensitivities (S_{HL} and S_{CL}) are shown. Shaded regions indicate temperature ranges over which load is minimally sensitive to changes in ambient temperatures.

rate at which energy consumption increases with air temperature in summer or decreases with temperature in winter. The U-shape of these curves demonstrates the reversed role that ambient air temperature has in winter vs. summer. It also reveals that during shoulder seasons (e.g., Fall and Spring) building energy consumption reaches a minimum value, which can be thought of as the weather-independent base-load (BL). The shaded regions indicate temperature ranges over which utility loads are relatively insensitive to changes in ambient temperature. These regions are centered on nominal threshold temperatures for the winter and summer peaking utilities, $T_{\mathrm{DD,w}}$ and $T_{\mathrm{DD,s}}$, respectively.

To simplify the relationship between ambient temperature and utility system or individual building energy loads, energy analysts have long used two parameters that characterize the ambient temperatures in a city as they relate to demand for heating and cooling of buildings. These metrics are heating and cooling degree days (HDD and CDD, respectively). They are defined in such a way as to account for the fact that heating demand in most cities approaches zero for ambient air temperatures above some threshold (T_{HDD}) and cooling demand approaches zero for ambient air temperatures below a cooling threshold (T_{CDD}).

$$\mathrm{CDD} = \sum \frac{1}{2}[(T - T_{\mathrm{CDD}}) + |(T - T_{\mathrm{CDD}})|] \qquad [5]$$

$$\mathrm{HDD} = \sum \frac{1}{2}[(T_{\mathrm{HDD}} - T) + |(T_{\mathrm{HDD}} - T)|] \qquad [6]$$

The first and second terms on the right side of each of these equations only differ by the use of absolute values for the second terms. Thus, the form of these expressions results in no increment to the degree day calculation for periods during which the ambient temperature is either warmer or colder than the HDD or CDD threshold temperatures, respectively. These expressions should be evaluated using hourly temperature data, although in many instances daily mean temperature data are used. The actual values of the threshold temperatures vary from city to city, in part due to acclimatization of populations to warm or cool temperatures, and in part due to differences in building characteristics. Furthermore, the heating and cooling thresholds within any particular city may differ from each other, resulting in a temperature regime (between T_{HDD} and T_{CDD}) with relatively little demand for heating or cooling (the shaded boxes in **Figure 3**). For the sake of simplicity, most heating and cooling analyses in the United States use a common cooling and heating threshold temperature of $T_{\mathrm{DD}} = 65\ ^\circ\mathrm{F}$ (18 °C). It is important to note, however, that this is not an international standard. For example, in China it is common to use 26 °C as the threshold temperature for cooling (Zhang et al. 2002). It is therefore challenging to compare degree days from one country to another unless the raw temperature data from reliable weather stations are reanalyzed using a common base temperature. **Table 1** presents representative degree day data for a number of U.S. cities, using 65 °F as a threshold for both HDD and CDD. With CDD and HDD as metrics for evaluating the weather-sensitive component of energy consumption in buildings it thus becomes easier to compare buildings in differing climate regions. In the absence of significant differences in building infrastructure and human behavior one would expect energy consumption for heating and cooling to scale with degree days (Scott et al. 1994; Sailor and Munoz 1997).

Table 1 Normal annual heating and cooling degree days (65 °F base) for U.S. cities for the period 1961–91 (from NOAA 2008). These data are commonly presented in units of °F days. To convert to °C days (with 18 °C base) these values must be divided by 1.8

City	*Annual heating degree days (base 65 °F)*	*Annual cooling degree days (base 65 °F)*
Atlanta, GA	2827	1810
Chicago, IL	6493	835
Denver, CO	6128	695
Houston, TX	1525	2893
Los Angeles (Airport), CA	1286	682
Miami, FL	155	4383
New York (Central Park), NY	4744	1160
Phoenix, AZ	1040	4355
Sacramento, CA	2666	1248
Seattle (Airport), WA	4675	173

It is important to recognize, however, that interactions between the energy sector and climate extend far beyond the simple temperature-dependence of demand just discussed. One of the most telling stories of energy sector vulnerability to multiple environmental stressors is that of the March 2011 earthquake and resulting Tsunami that hit the eastern coast of Japan. The devastation caused by the flooding forced the shutdown of the Fukushima Daiichi nuclear power plant which had an installed capacity of 4696 MW and provided an annual electric power generation of nearly 30 000 GW-h for the region. The shortfall in generation capacity resulted in 3-h rolling blackouts throughout Japan, starting directly in the aftermath of the disaster. The energy-related ramifications of this disaster were further exacerbated by the increasing electricity demand as the weather warmed into the summer months. Fortunately, in efforts to avoid more drastic blackouts during the hot summer months, Japan was able to use demand management strategies to reduce peak demand for 2011 by 18% relative to the summer of 2010. This incident demonstrates not only the important interacting roles of multiple coincident environmental stressors acting in concert, but also the resiliency inherent in the system via social and economic drivers.

Long-term climate variability and change will affect the energy sector in many complex ways beyond the simple weather-sensitivity of HVAC loads. For example, changes in frequency and magnitude of precipitation events combined with a warmer climate will likely strain water resources, which are linked to energy resources. For example, fossil fuel and nuclear power plants require large amounts of cooling water. Furthermore, environmental restrictions limit the amount of heat such plants can release into lakes and rivers, and such restrictions are likely to be more challenging, as these thermal reservoirs heat up due to any changes in climate statistics. Also, hydroelectric and biofuel-based power generation is tightly coupled to the hydrologic cycle and in competition with other demands for fresh water supplies (agriculture, drinking water, recreation).

3.12.3.2 Construction Characteristics, Behavior, and Management Practices

There are many complex relationships affecting energy consumption by buildings and their occupants. The role of human behavior is complicated, as it is influenced by building construction characteristics and interacts with large-scale social norms, and management practices. Thus, these interrelated factors are discussed together in this section.

Infrastructure plays a significant role in affecting energy use in buildings. Two buildings in the same climate with similar occupants and functions can have vastly different energy use resulting from differences in construction quality, insulation levels, glazing-to-wall surface area ratios and equipment efficiencies. Building-to-building variations within a city are largely driven by variations in building vintage, which in turn reflects the differing building codes in force at the time of construction, as well as relative improvements in efficiencies of building equipment. For example, many U.S. states implement building code upgrades periodically that mirror, but lag, updates in national standards (e.g., ASHRAE 2007) or international model codes (ICC 2009). Variations from one city to another or from one country to another reflect the relative energy efficiency sophistication of building codes and management practices within the building industries. These differences are further influenced by differing social attitudes, economic priorities, and the relative severity of summer and winter weather conditions.

While there is a rich history of data and analyses of building stock characteristics, energy consumption, and energy standards in western countries (Scott et al. 1994; Huang and Brodrick 2000; EIA 2005; Bruhns and Wyatt 2011; Theodoridou et al. 2011) much of the current and future growth is in regions of the world with relatively nascent building energy efficiency efforts. Focusing on energy consumption within the residential and commercial building sectors, data from the International Energy Agency (IEA 2011) show a wide range of annual energy use per capita with Canada and the United States having among the most energy-intensive building sectors (81.4 and 65.4 GJ per capita, respectively). Europe tends to have lower consumption rates, with Germany, the United Kingdom, and Sweden consuming 49.7, 39.8, and 48.7 GJ per capita in their building sectors, respectively. Japan has an even lower energy consumption rate of 37.1 GJ per capita in its residential and commercial buildings. While some of the differences in these energy use intensities result from climatic differences, much is due to the differences in social and economic factors.

Of course, the tremendous recent and forecasted growth in India and China brings to the forefront questions related to how those countries will develop and deploy more stringent building energy efficiency standards. While their building sectors currently only consume 6.6 and 12.4 GJ per annum per capita, it is likely that these energy use intensities will substantially increase in coming decades. A study in 2007 suggested that the Chinese government's own statistics on commercial building energy consumption underestimated commercial energy consumption by 44% (Bressand et al. 2007). Nevertheless, recent analyses conclude that commercial buildings in China are substantially less energy intensive than buildings in corresponding climate zones in the United States The explanation for this includes multiple related factors. First, commercial buildings in China generally provide a lower level of service related to maintaining thermal comfort. It is common, for example, for office buildings in China to use air conditioning only when the outdoor air temperatures are above 26 °C – a much higher cooling threshold (by about 8 °C) than in western countries. Furthermore, due to relatively lower labor costs, buildings in China may be more carefully managed than typical buildings in North America and Europe.

3.12.4 Adverse Effects of Energy Consumption in Buildings

Buildings play a crucial role in improving quality of life of occupants by isolating them from unpleasant outdoor conditions and providing safe environments for work, rest, and recreation. The energy used to provide these benefits in the indoor environment, however, ultimately affects the outdoor environment through waste heat and pollution emissions.

3.12.4.1 Buildings as a Key Determinant of Peak Utility Loads and Capacity Requirements

In developed countries, buildings are typically the dominant energy-consuming sector, and are by far the largest consumers of electricity in any city. As a result, buildings play a key role in dictating peak electricity loads, which in turn dictate the requirements for electric energy generation capacity (power plant MW). Energy consumption in buildings can be divided into two categories – base load for activities that are independent of ambient weather and weather-sensitive load for heating and cooling applications. While the base load has diurnal fluctuations that track human activity – peaks in the early morning and late afternoon – the weather-sensitive loads can introduce perturbations that are several times as large as the variations in the base load. This is particularly true in the summer for cooling-dominated climates where electricity loads associated with air conditioning demand in buildings define the timing and magnitude of peak consumption. As demand for electricity increases utilities are forced to ramp up reserve power plants. Under extreme conditions, the utility generation-transmission infrastructure may be incapable of meeting total demand, necessitating the implementation of demand management strategies to throttle back load. In such cases, the risk of electricity brownouts and blackouts increases. For example, an extreme heat wave in Western North America on 10 August 1996 buckled the Western Intertie resulting in power outages for millions of customers across nine Western States and portions of Mexico (NWPCC 2011). While extreme heat, winds, and other weather-related phenomena are significant direct contributors to power grid reliability issues, they often represent indirect causes or triggers for failure. For example, the great Northeast United States blackout of August 2003 was triggered by several failed transmission lines near Cleveland Ohio, which resulted in a cascade of system failures across Northeast United States and into Canada, affecting over 10 million people. The failure appears to have been precipitated by heavy demand on several transmission lines which caused them to overheat, sag, and come into contact with trees (US-CAN 2004). Similar large-scale blackouts in Brazil and Paraguay in November 2009, Italy in September 2003, and elsewhere have been attributed to wind, rain-snow events that triggered cascades of failures.

Building resiliency into the energy supply infrastructure is one of the grand challenges faced by modern society. Regional and international pressure to reduce reliance on fossil fuel based power plants is introducing renewable energy into the fuel mix at ever increasing levels. The climate-dependency and intermittency of such supplies and challenges associated with transmission and storage limitations is just now being felt by energy providers. For example, in Spring 2011 the Northwest United States had high levels of snow pack and associated runoff to be handled by its hydroelectric facilities that coincided with high wind resource. The transmission system could not handle the excess supply and as a result the Bonneville Power Administration (BPA) refused to purchase wind power from facilities in the region. The alternative would have been to allow hydroelectric capacity to flow unused over dam spillways, with the associated loss of free electric power, and potentially adverse effects on fish populations associated with the resulting increase in dissolved gas in their aquatic habitat. As wind power and solar power facilities become more prevalent, scenarios such as this will likely be repeated. While much of the solution to these challenges will come from improved transmission infrastructure and new energy storage technologies, there is no question that the building sector can be part of the solution through improved end-use efficiency and management strategies.

3.12.4.2 Waste Heat Emissions from Building Energy Use

If one considers a control volume drawn around a building it is possible to trace all flows of energy into and out of the building. As noted previously, energy interacts with a building in the forms of incident solar radiation, long-wave radiant exchange with the sky, and other surfaces; convection (and infiltration) of heat to/from outside air; and generation of waste heat associated with the use of electricity and end-use combustion processes within the building. While the building itself stores heat diurnally and seasonally, it is reasonable to consider the building as being in pseudo steady-state. That is, any energy crossing the building envelope must be rejected to the environment. While some of this rejected heat is in the form of waste heat entering the sewage stream, most of it is in the form of sensible and latent heat rejection to the urban atmosphere.

The magnitude of sensible waste heat emissions from a building varies across the seasons and depends upon the type of mechanical cooling it employs (Heiple and Sailor 2008). For a small office building with a sensible air-to-air heat exchange system the total sensible waste heat in summer can be much larger than the total building energy consumption – due to the need for the HVAC system to reject environmental loads in addition to rejecting loads associated with internal energy consumption. In contrast, if the building is cooled through use of evaporative–cooling towers, then much of this heat load is rejected from the building in the form of latent heat. The magnitude of this waste heat emission depends upon the environmental factors noted above, as well as building construction details, building equipment, and characteristics of energy use within the building. According to the U.S. Department of Energy the average annual energy consumption across all commercial building types in the United States is roughly 90 kBTU ft^{-2} ($\sim$280 kWh m^{-2}). To put this in context, consider the solar radiation incident on a city over a year. Data from NREL indicate that the solar insolation ranges from about 3.0 to 6.0 kWh m^{-2} per day for most mid-latitude cities (NREL 2011). On an annual basis this corresponds to about 1000–2000 kWh m^{-2}. So, a typical six-story commercial building in the United States consumes an amount of energy (electrical and natural gas) that is comparable in magnitude to the total solar radiation incident on the building site. This is precisely why the goal of developing net-zero energy consumption buildings is so challenging. With the highest efficiency photovoltaic systems only on the order of 20% efficient any realistic net-zero energy project for a multi-story building must meet the net-zero goal by a combination of reducing EUI, employing efficient energy exchange-storage strategies such as geothermal wells, as well as extensive deployment of photovoltaic power generation on site.

There is no doubt that buildings are responsible for sizable emissions of heat and moisture. The important question, however, is how do these emissions affect the urban climate system. Qualitatively it is apparent that such emissions should increase the magnitude of the UHI and increase humidity levels. But how these increases in temperature and humidity affect quality of life for the urban resident depends on multiple factors. First, there is a clear differentiation between the implications of these emissions in summer vs. winter. Whereas added heat in summer may not be desirable in many mid- and low-latitude cities, it may actually be beneficial in winter, particularly in mid- and high-latitude cities.

While actual quantification of anthropogenic heat release from buildings, vehicles, and industry remains an uncertain science, many studies have explored the effects of anthropogenic heat emissions on the urban climate of cities (see Sailor 2011 for a review of such studies). For example, a study by Torrance and Shum (1975) used inventory estimates of annual energy consumption to estimate waste heat associated with energy consumption in a city. They found this heating to be as large as 135 W m^{-2} and used a simplified transient one-dimensional atmospheric model to assess its atmospheric consequences. They found that this level of anthropogenic heating could result in up to a 4 °C warming of near-surface air temperatures in summer. In a study involving a more sophisticated representation of anthropogenic heating in Tokyo, Kimura and Takahashi (1991) used detailed land use and energy consumption data to estimate anthropogenic heating and its impact on urban air temperatures. Peak anthropogenic heating from that analysis was on the order of 100 W m^{-2}. Using these sensible heat emissions as a source term in a three-dimensional atmospheric model they then found that much of the nocturnal summertime heat island in Tokyo (2–3 °C) is due to anthropogenic heating.

Ichinose et al. (1999) used energy statistics for various building types and end uses in Tokyo and detailed digital land use data to estimate hourly anthropogenic heating on a much finer grid resolution of 25 m by 25 m. As is to be expected, the high spatial resolution led to some rather large estimates of heating associated with grids that were centered on large high rise office buildings. Recall, that the energy use in a typical six-story commercial building can rival the sun's energy input averaged over the footprint of the building. Ichinose found that hourly energy consumption at this fine scale (assumed equal to anthropogenic sensible heating) could be as large as $1590\,\mathrm{W\,m^{-2}}$ in the winter and was more than $400\,\mathrm{W\,m^{-2}}$ during summer daytime hours. His analysis also integrated these estimates of anthropogenic heat into a regional atmospheric model simulation. The result was a summertime air temperature elevation of about 1 °C during the day, and as much as 1.5 °C at night. In winter, when the magnitude of anthropogenic heating was much higher the nocturnal warming reached 2–3 °C.

Fan and Sailor (2005) implemented city-scale estimates of anthropogenic heat emissions for Philadelphia, Pennsylvania (obtained from Sailor and Lu 2004) into a mesoscale atmospheric model. That study found peak anthropogenic heating at the city scale to be $60\,\mathrm{W\,m^{-2}}$ in summer and approximately $90\ \mathrm{W\ m^{-2}}$ in winter. The impacts of this anthropogenic heating on urban air temperatures ranged from 1 °C in summer to 3 °C in winter.

Thus, in aggregate, these studies suggest that anthropogenic heating in cities can be on the order of $100\text{–}1000\ \mathrm{W\ m^{-2}}$, easily rivaling the energy input from the sun. Furthermore, this level of waste heat emission into the urban atmosphere can raise local air temperatures by 1–3 °C depending upon time of day and season. Clearly, one limitation of this prior work is the reliance on crude inventory-based estimates of anthropogenic heating that assumes energy consumption is equal to anthropogenic sensible heat release. Also, modeling of anthropogenic heat effects on the urban atmosphere is generally accomplished using regional scale atmospheric models that do not resolve buildings or the urban canopy within, which the emissions are assumed to mix (and some emissions occur at significant elevation from rooftop HVAC equipment on tall buildings). A third limitation is the general inability to obtain observational validation of the results of the modeling studies. Nonetheless, it is reasonable to conclude that waste heat emissions associated with energy use in buildings can have a significant effect on urban air temperatures.

3.12.4.3 Air Quality Implications of Urban Energy Use

Energy use in buildings affects both indoor and outdoor air quality. While much of the focus when it comes to urban air quality is in the outdoor environment, it must be noted that typical urban residents spend more than 75% of their time indoors (e.g., 8 h sleeping, 8 h working, and 2 or more hours of other indoor activities such as eating). So, from an exposure standpoint, the indoor air quality is at least as important as the outdoor air quality.

The primary air quality concerns indoors are associated with elevation of CO_2 levels, mold spores, volatile organic compounds (VOCs), and CO associated with indoor combustion sources. In efforts to reduce exposure to indoor air pollutants various building design and ventilation standards have been developed over the years. Chief among these is ASHRAE 62.1, which dictates a nominal ventilation rate of 15 CFM (cubic feet per minute) or $0.44\ \mathrm{m^3}$ per minute for each building occupant (ASHRAE 2010). The implication of such ventilation standards is that indoor air must be continuously replaced with 'fresh' outdoor air. While some buildings may meet this requirement passively through infiltration, most classes of commercial buildings meet this standard through mechanical ventilation, which also requires additional energy consumption for conditioning of the outside air. Such ventilation results in the exchange of indoor and outdoor air pollutants, and heat.

Energy use in buildings also contributes to outdoor urban air quality problems via the power plant emissions associated with delivering electricity to buildings. Energy use in buildings can influence outdoor air quality in cities in other more subtle ways also. For example, since the emission of waste heat from buildings warms the urban environment it affects the rate constants in many of the equations that influence the formation and destruction of tropospheric ozone. The elevated urban air temperature also affects emissions of pollutants from both biogenic and anthropogenic sources. Under warm atmospheric conditions, an increase in air temperature results in higher levels of hydrocarbon emissions (isoprene, monoterpenes) from vegetation. While this relationship is highly variable across plant species the sensitivity of biogenic emissions to increasing air temperatures is generally on the order of 5% per degree Celsius (Benjamin et al. 1996; Taha et al. 1998). Of course, under situations of extreme temperature stress (typically air temperatures above 38 °C) plant stomata begin to close up and the rate of biogenic emission can actually decrease as air temperature further increases.

Tropospheric ozone (O_3) and fine particulate matter (nominal sizes 2.5–10 μm – $PM_{2.5}$ and PM_{10}) are EPA-regulated criteria pollutants known to have detrimental health effects, including heart and lung disease, respiratory disease, and decreased lung function. Ozone is formed by chemical reactions involving oxides of nitrogen (NO_x) and volatile organic compounds (VOC) in the presence of sunlight. The precursors of ozone come from a range of anthropogenic sources including on-road motor vehicles, off-road vehicles, fugitive emissions, area sources, chemical solvents, power plants, and point sources. VOC emissions also come from biogenic sources. Particulate matter is generated both directly in the form of dust and soot from combustion processes and indirectly through reactions within the atmosphere (notably the formation of sulfate aerosols from SO_2 emissions at power plants, nitrates formed from NO_x, and organic aerosols in urban environments).

Both ozone and PM are influenced by a complex array of meteorological parameters that affect emissions, atmospheric chemistry, and transport (Bornstein and Thompson 1981; Sillman and Sampson 1995). Meteorological conditions are, in turn, affected by concentrations of ozone and PM. Atmospheric production of ozone and PM is strongly affected by ambient temperature (Vukovich 1994; Hubbard and Coburn 1998; Aw and Kleeman 2003) as a result of many interrelated factors, including the temperature sensitivity of emissions and reaction rates for relevant processes such as the decomposition of PAN (peroxyacetylnitrate) – an influential series of reactions in ozone formation. At the same time, higher temperatures can enhance the production of turbulent kinetic energy, vertical mixing, and the depth of the boundary layer (i.e., resulting in decreased concentrations). This relationship is further complicated by the local VOC:NO_x ratio which can lead to either decreases or increases in ozone concentrations depending on local conditions. Thus, waste heat emissions from buildings can influence the formation of ozone and PM in the urban airshed.

The water vapor mixing ratio also has a complex role in the photochemical production of ozone. On one hand it acts as a sink for NO_x and VOC (slowing the formation of ozone), but it is also a source for OH radicals (via chemical reaction with O) that together with NO_x act as catalysts for ozone formation (Singh et al. 1995; Muller and Brasseur 1999). Thus, the vast emissions of moisture from cooling towers that are commonly employed in larger commercial buildings may also contribute to this complex chemistry related to production of ozone.

3.12.5 Strategies for Sustainable Urban Development

Urban planners and regional government authorities are concerned about a host of environmental issues associated with urban development. These environmental challenges include local concerns such as air quality, water quality-availability, and energy availability. They also include more global concerns such as a city's contribution to global climate warming. The various policies, initiatives, and regulatory efforts that have been developed to address these issues are correspondingly diverse. These efforts include strategies to reduce energy consumption or shift energy production to cleaner sources. They also include efforts to modify surface characteristics through plot-level and city-scale development policies and regulations. Each strategy, regulation, or policy has the potential not only to affect its intended end point, but also can have unintended consequences in other aspects of the urban climate system. So, while the focus of this chapter is the many complex interactions between the urban climate system and building energy use, we must not lose track of the fact that there are many other aspects of the urban environment that also interact with these systems.

3.12.5.1 Building Energy Codes, Standards, and Rating Systems

Requirements for building construction are usually dictated by building codes developed and enforced at local or state levels. There is generally a code for the structural aspects of the building and a separate code for the energy performance characteristics. Energy codes are further differentiated by class of building (commercial or SFR) and climate zone. Energy codes are written in mandatory and enforceable language. They are typically informed by energy standards, which are guidelines or recommendations published by national organizations such as ASHRAE. Standards are routinely updated based on new findings in building science and technological innovations. The update cycle for the ASHRAE standard is 3 years. This standard makes recommendations regarding building characteristics such as insulation levels and equipment efficiencies, which can significantly affect building energy consumption. Further, it references other standards for a subset of specific characteristics such as ventilation. In an effort to provide a model energy code that can be readily adapted and implemented by local jurisdictions the International Code Council (ICC) updates their International Energy Conservation Code on a 3 year cycle. Many U.S. states have state energy codes that are based on some version of ASHRAE 90.1 or the IECC. In some cases, most notably California with its Title-24 energy code, the state code is more stringent than the current versions of ASHRAE 90.1 and IECC.

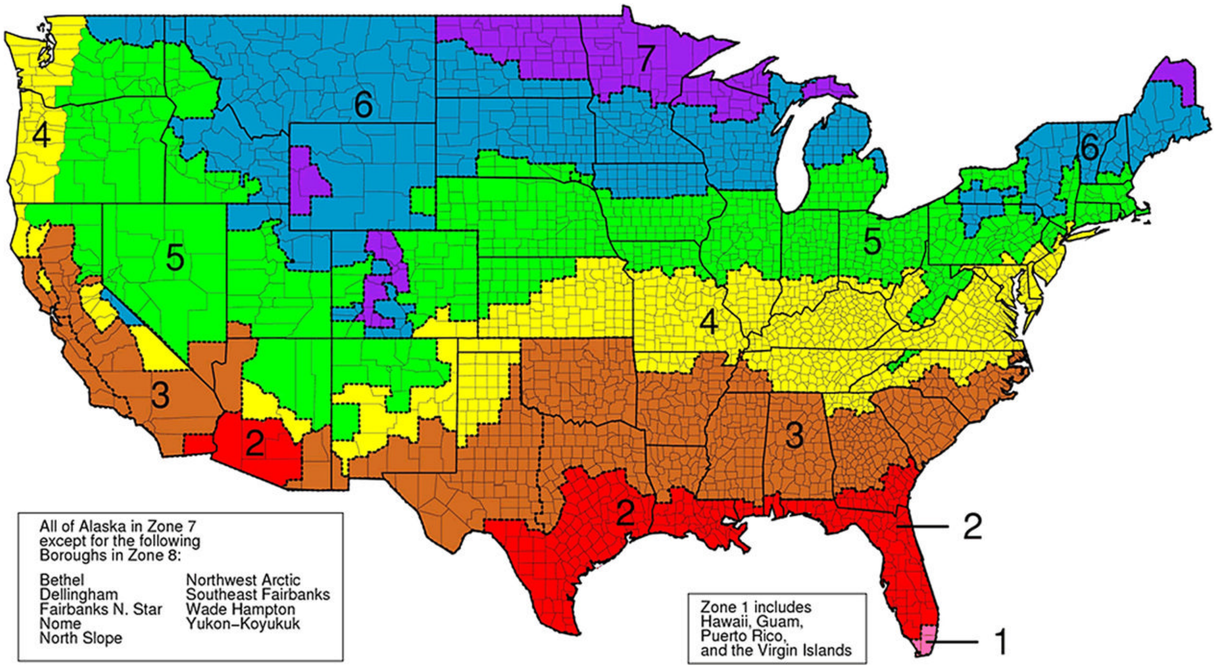

Figure 4 ASHRAE 90.1 climate zones in the United States. Reproduced from ASHRAE, 2007: *Standard 90.1: Energy Standard for Buildings Except Low-Rise Residential Buildings.* American Society for Heating, Ventilation, and Air-Conditioning Engineers, Inc, Atlanta, GA.

To account for variations in climate that differentially affect heating and cooling demand various energy codes and standards have different specifications for climatically different regions. ASHRAE 90.1 and IECC, for example, both define eight climate zones as illustrated in Figure 4. While all of California falls into five of these categories (2, 3, 4, 5, 6) the state of California in its Title-24 energy code uses a refined classification system that divides the state into 16 climate regions.

Beyond building codes there are also a host of voluntary standards and rating systems. For example, the Building Research Establishment's Environmental Assessment Method (BREEAM) was established in the United Kingdom in 1990 as a voluntary rating system for green buildings and is updated regularly. France has a similar standard – the Haute Qualite Environmentale (High Environmental Quality) or HQE – introduced by the Centre Scientifique et Technique du Batiment (CSTB). Australia has its Green Star rating system launched in 2003 by the Green Building Council of Australia. Leadership in Energy and Environmental Design (LEED), developed by the U.S. Green Building Council, is popular in the US, but has been applied to buildings in many countries. Green Globes, developed by the Green Building Initiative – a Portland, Oregon-based nonprofit – is also a popular rating system that has been widely used in Canada. Other rating systems exist around the world. All tend to have common features related to assessing building energy efficiency. They establish a baseline reference building and then rate a current building design with respect to its predicted or actual energy consumption. One drawback of most such rating systems is that building energy assessment is based on predictive energy simulation models rather than being based on actual (post-occupancy) performance. Actual building energy performance can deviate significantly from such predictions as a function of how well individual systems actually perform (typically determined through building commissioning), and how building occupants and managers interact with the building's systems (Newsham et al. 2009; Scofield 2009).

As these codes, standards, and rating systems evolve in conjunction with government initiatives they continue to move the building industry toward net-zero energy buildings of the future. Of course, regardless of the pace of such improvements in energy standards, the longevity of existing buildings will inevitably temper the pace of reduction in energy use across the entire building sector. Many individual systems such as roofing membranes and mechanical equipment have lifespans ranging from 15 to 30 years. The lifespan of the building itself varies substantially, but can range anywhere from several decades to more than 100 years. Thus, in the absence of deep retrofits, the penetration of new technologies and new building energy codes and standards has a correspondingly long time scale. Nevertheless, new codes and government initiatives hold promise for substantially reducing the energy consumption of new buildings. For example, the California Energy Commission has a stated goal of having net-zero new construction in the residential sector by 2020 and net-zero energy consumption in new commercial construction by 2030. This and similar efforts around the world have been motivated by concerns over fossil-fuel contributions to climate and grand initiatives such as Architecture 2030, which seeks carbon neutral new buildings by 2030.

3.12.5.2 Innovations in Transmission and Distribution of Energy

The significant challenges of delivering electricity to an ever-urbanizing world subject to the stresses of climate, population growth, and increasing per capita consumption is stretching capacities both in terms of power generation and transmission infrastructure. Aside from end-use efficiency, cities and regions are increasingly turning to new promising solutions. One approach that has received tremendous attention in the popular media is the notion of the 'smart grid.' The smart grid includes several interconnected components. First, is improved transmission–distribution of electrical energy through use of digital technology to enable real-time management of transmission networks. These modernized networks are then linked to management of end-use loads through smart meters and grid-enabled appliances, which exchange information with the grid, reducing or delaying energy consumption in response to price or load signals from the smart grid. To the extent that such technologies reduce and shift peak loads, they also shift the associated waste heat emissions. While innovations in the electric utility infrastructure will take place at regional scales, and building energy use improvements will take place at the building scale, there will likely also be innovations at the neighborhood scale. For example, there is growing interest in district heating and cooling strategies. District heating and cooling replaces individual chillers and boilers in buildings with a central facility that provides steam or chilled water to a small network of buildings located in close proximity. Such systems can improve overall efficiency for the neighborhood and also reduce capital costs of equipment, but they result in a centralized and concentrated emission of pollutants and waste heat.

3.12.5.3 Urban Design, Land Use, and Surface Characteristics

The characteristics of urban design that are most influential in the urban climate system include infrastructure characteristics such as the morphology of buildings that comprise the urban landscape (e.g., heights of buildings, widths of 'canyons' between buildings), and surface characteristics ranging from rooftop albedo to street-level vegetative cover and prevalence of impervious surfaces. Changes to these characteristics affect energy consumption in cities through both direct mechanisms (e.g., reduced heat conduction through highly reflective roofs), but also through indirect mechanisms (e.g., higher vegetative cover in a city can reduce air temperature, leading to reduced air conditioning demand via mechanisms of convection and infiltration).

Urban vegetation and albedo have long been strategies investigated for UHI mitigation (e.g., Rosenfeld et al. 1995; Taha et al. 1998; Taha and Sailor 1997). The motivation for studying these strategies arises directly from the surface energy balance for a city. For example, consider a control volume around the air of a city as illustrated in Figure 5, where Q^* is the net radiation term, Q_L is the latent heat flux from the urban surface, Q_H is the sensible heat flux from the urban surface, Q_A is the net advection of heat (enthalpy) into the control volume, Q_G is the conduction of heat into the substrate (including building materials), and Q_F is the anthropogenic heat

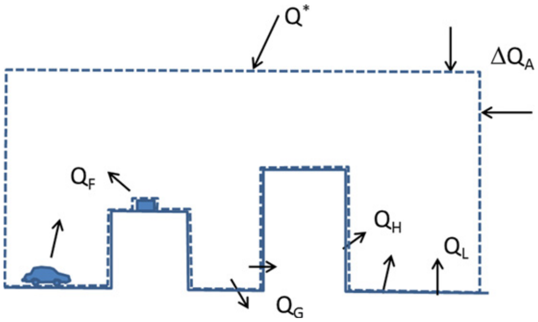

Figure 5 Key contributors to the energy balance of an urban surface (ground, walls and roofs) and the volume of air (bounded by the dashed line) above the urban surface.

generation which can be treated as a source term in the control volume. The net radiation term encompasses incoming and outgoing energy both in the short wave spectrum (solar radiation) and the long wave spectrum (thermal radiation). Depending upon time of day and season, this net radiation term, which includes incoming, emitted, and reflected components may be positive or negative. Most of this radiant energy is transmitted through the urban canopy air volume (defined here as being nominally twice the average building height above the ground surface), with a small amount being absorbed directly by the air molecules in this layer. The sensible and latent heating terms account for convection and evapotranspiration processes at the surface, respectively. Some sensible and latent heat crosses the control volume as part of the net advection term. The anthropogenic heat flux term can be thought of as a source term in the volume that accounts for emission of heat from vehicles, building HVAC systems, and other sources, including human metabolism of individuals within the street canyons. The rate of rise of air temperature in the control volume can then be computed from the sum of the sensible forms of heat fluxes into the air volume:

$$\rho C V \frac{\partial T}{\partial t} = Q_F + Q_A + Q_H \tag{7}$$

where ρ is the air density, C is the specific heat, V is the air volume, $\partial T/\partial t$ is the time rate of change of air temperature in the volume. In this equation Q_F, Q_A, and Q_H are rates of heat addition for anthropogenic heat, advection, and sensible heat exchange processes, respectively. All are in units of W.

It should be noted that evaporation and transpiration processes can be significant contributors to the surface energy balance (Q_L), but are only indirectly reflected in the above temperature evolution equation through their influence on other components of the volumetric energy balance. Likewise, net radiation (Q^*) is not directly included in this equation, although it plays a driving role in affecting surface sensible flux, and also can contribute to a modest amount of warming of the air through absorption of radiative energy within the air column (ignored here for simplicity, but treated as a volumetric source term in a thorough treatment of the energy balance). Thus, in evaluating the role of the urban surface in the elevation of urban air temperatures and heat island development it is also important to consider the surface energy balance, which results from Figure 5.

$$Q^* = Q_H + Q_L + Q_G \tag{8}$$

Again, in this expression each term must be expressed in units of W. This is necessary as the corresponding fluxes [W m^{-2}] each act over different surface areas. It must also be recognized that the values of each heat flux vary in space (and time) across the urban surface (e.g., there is very little storage heat flux Q_G into window glass, higher sensible heat fluxes from warmer surfaces, etc). In practice, eqns [7] and [8] are solved in fully three-dimensional atmospheric models, subject to atmospheric initial and boundary conditions and with the aid of boundary-layer parameterizations that evaluate the sensible and latent heat flux terms as functions of atmospheric stability. When including anthropogenic heating in the surface air energy balance it must be noted that the vertical distribution of anthropogenic heat emission is important. Specifically, while vehicles emit heat into the air at pedestrian level, emissions from a building occur throughout the vertical height of the building, with a substantial portion occurring at the location of the mechanical HVAC equipment – often located on the roof. Thus, while vehicle emissions of anthropogenic heat may be considered to be well mixed within the urban canopy, heat and moisture emissions from the building sector occur within and above the urban canopy. As a result, some of the building's anthropogenic emissions may have little impact on the air temperatures within the canyon.

There are several methods for investigating the urban air temperature sensitivity to changes in surface parameters, and, hence, the efficacy of UHI mitigation measures. These include field measurements in full-scale deployments of mitigation measures and computer simulation of simplified scenarios of surface modification. Both have significant limitations. For example, in conducting large-scale controlled experiments to explore the effects of heat island mitigation strategies such as increasing surface albedo across the city, it is difficult to measure resulting effects on neighborhood air temperature which may be small relative to measurement uncertainties and spatial variability. Furthermore, it can be difficult to attribute measured differences in air temperatures to a particular surface modification when many other factors (e.g., synoptic weather, anthropogenic emissions) covary. Nevertheless, some researchers have investigated UHI mitigation measures indirectly by making detailed urban air temperature measurements in conjunction with statistical analyses of land use and land cover variation across the city (e.g., Hart and Sailor 2009). The resulting regression models can provide insight into the potential for surface modification to reduce the magnitude of the UHI.

Numerous studies have tried to estimate the efficacy of UHI mitigation strategies by using regional scale (mesoscale) atmospheric models. Such efforts are inevitably limited by the inability of most regional models to resolve individual buildings and the complexities of heat transfer and fluid flow within the urban canopy. Rather, such studies often apply a simple uniform change to a surface characteristic such as albedo and compare the resulting 2-m predicted air temperature with that predicted by the model prior to the surface modification. While canopy-layer and computational fluid dynamics models can resolve effects of surface modification on near surface air temperatures within realistic urban canopies, they generally have simplified coupling with regional climate, and so estimation of regional-scale effects of large-scale UHI mitigation is still limited.

Morphology of urban canyons – building height to canyon width ratios – also has the potential to affect near-surface environmental conditions and the UHI more generally. This occurs through a combination of three factors. First, tall buildings provide shading to the urban surface below so that much of the radiative load from the sun is intercepted by building roofs and exterior walls. Depending upon the albedo of roof-wall surfaces and the fractional window area and glazing characteristics, this radiative load is largely reflected out of the urban canyon, or conducted-transmitted into the building – later reentering the urban energy balance at the location of the HVAC heat exchangers (e.g., roof-mounted packaged air conditioning units). The second role that morphology plays in the urban energy balance is that of affecting the exchange of long wave radiation among multiple urban surfaces and the sky. As a result, the floor of the urban canyon tends to remain warmer at night than its nonurban counterpart. Finally, the layout of buildings in a city can significantly affect transport of pollutants and the ventilation of urban canyons, depending upon their orientation relative to the prevailing wind direction. Through these mechanisms the morphology of urban canyons can be an important factor in determining street-level climatic conditions. For example, simulations conducted by Emmanual and Fernando (2007) found that high-density development was more effective than high-albedo UHI mitigation in terms of overall reductions in air temperature and mean radiant temperatures within an urban canyon. It is important to note, however, that compact development – as with any sustainable development strategy – has both beneficial and detrimental consequences. For example, deeper urban canyons can result in more stagnant air mass near the surface and correspondingly higher levels of pollutants.

3.12.6 Vulnerabilities and Opportunities Moving Forward

It should be clear from the preceding discussion that there are many complex interactions between the urban climate system and energy use in the building sector. Climate variability and climate change affect energy consumption for heating and cooling. The energy use in buildings provides a feedback mechanism whereby the urban climate is further perturbed. Additionally, energy use in the building sector has regional and global climate consequences associated with the emissions of pollutants, including carbon dioxide, from power plants.

The multitude of interconnections between energy and climate suggests a need to tread carefully with respect to physical or social engineering of the urban climate system as societies attempt to mitigate the adverse environmental consequences of development. For example, UHI mitigation efforts intended at reducing air temperatures for the purpose of reducing heat-related morbidity and mortality may result in thinner mixing heights over urban areas. Under such conditions, any moisture emissions at the surface are then mixed into a smaller volume of air, resulting in higher levels of near-surface humidity – and a mechanism for increasing heat-related morbidity and mortality, despite reductions in air temperatures. Likewise, UHI mitigation may inhibit ventilation of the urban canopy, creating a mechanism for worsening air quality. There are numerous other examples where UHI mitigation strategies may have unintended consequences. Thus, it is particularly important that as urban climate mitigation-adaptation policies and initiatives are proposed, they should be scientifically, socially, and economically vetted in terms of their potential wide-ranging consequences – intended or otherwise.

Glossary

Diesel particulate filter (DPF) A device designed to remove diesel particulate matter from the exhaust gas of a diesel engine.

Greenhouse effect The phenomenon whereby the Earth's atmosphere traps solar radiation, caused by the presence in the atmosphere of gases such as carbon dioxide, water vapor, and methane that allow incoming sunlight to pass through but absorb heat radiated back from the Earth's surface.

Plug-in hybrid vehicle (PHV) A hybrid vehicle that utilizes rechargeable batteries, or another energy storage device, that can be restored to full charge by connecting a plug to an external electric power source (usually a normal electric wall socket).

Sustainable development Development that meets the needs of the present without compromising the ability of future generations to meet their own needs. It contains within it two key concepts: (1) the concept of needs, in particular the essential needs of the world's poor, to which overriding priority should be given and (2) the idea of limitations imposed by the state of technology and social organization on the environment's ability to meet present and future needs.

Sustainable transportation Transportation that refers to any means of transport with low impact on the environment.

Three-way catalyst (3WC) An oxidation–reduction catalytic converter installed in the exhaust pipe system of gasoline vehicles. It is designed to do three simultaneous tasks: (1) Reduction of nitrogen oxides to nitrogen and oxygen, (2) Oxidation of carbon monoxide to carbon dioxide, and (3) Oxidation of unburned hydrocarbons (HC) to carbon dioxide and water.

Transportation fuel Any material (mainly gas or liquid) burned to produce power to motor vehicle.

> Surprised by joy – impatient as the Wind
> I turned to share the transport

3.13.1 Introduction

Secure, protected, clean, low-cost and affordable energy and transportation are substantive to the social and economic vitality of the world. Our quality of life is heavily dependent on economical, plentiful, and reliable supplies of energy; nearly everything that defines our way of life requires some sort of energy-consuming device. In parallel, few (if any) human activities seem more important to civilization than transportation and communication, and, apart from direct tyranny and oppression, nothing is more harmful to the well-being of a society than an irrational transportation system.

http://dx.doi.org/10.1016/B978-0-12-384703-4.00322-1

Growth in economic activity and population are the key factors that determine transportation sector energy demand. Transportation is an important part of economy and functions as one of its foundation, support, and service provider. Subsequently, modern mobile societies consume significant amounts of energy to support passenger travel and freight transport. In developing economies, increased economic activity leads to growing income per capita; and as standards of living rise, demand for personal transportation increases. More specifically, the magnitude of the mobility of persons and freight and the vast trip distances generated by such hypermobility makes transportation the fastest growing consumer of energy and producer of greenhouse gases (GHGs) (EC 2010; TRB 2011).

Energy for transportation vehicles can be supplied externally (e.g., sailboats, electric trains, trolleys) or carried on board (e.g., automobiles, jet aircraft). In the twentieth century, the internal combustion engine (ICE) became the predominant source of power for transportation vehicles, displacing animal, wind, and steam power. After a brief period of experimentation early in the twentieth century, liquid fuels derived from petroleum emerged as the clearly preferred form of energy for ICEs. These fuels have four key advantages: (1) they have high energy density per volume and weight; (2) they are easily handled and stored because they are liquid under ambient conditions; (3) throughout most of the twentieth century, petroleum resources have been in abundant supply; and (4) they are relatively inexpensive. By the middle of the twentieth century, petroleum supplied 90% of the energy for transportation vehicles and continues at the same percentage approximately.

Today, a variety of opportunities exist to alter future demand for transportation fuels, reduce emissions, improve energy security, and provide significant energy savings. On the engine front, they include all-electric, full hybrids, plug-in hybrids, and hydrogen fuel cell drive trains. On the fuel side, the path moves through dieselization, biofuels (i.e., ethanol, biodiesel), natural gas, and coal-to-liquid fuels and hydrogen. All of these go some way to address air quality problems and to make an impact on GHG emissions in the developed world. But it merely scratches the surface of the problems just outlined for the developing world, where climate issues fall low on its list of priorities. In this global framework, petroleum fuels seem to continue as the dominant transportation fuel in the short and medium term.

At the same time, the world is concerned about the transportation industry for its huge consumption of petroleum energy as well as for its environmental impact. Governments, the transportation industry, and experts participate in the discussion to explore alternatives. Policy makers are confronted with difficult decisions on how to respond to climate issues. Policy making in this field is particularly challenging because of the high degree of uncertainty encompassing this kind of decision making. Uncertainty pertains to several key factors: the impacts climate will have on nature, society, and the economy, and the cost and effects of policies designed for mitigation. In any case, the types of policy measures taken to satisfy treaty targets will have lasting impacts on the technology we use and could affect the way we live, consume, and travel.

In the following, based on the bottom-up approach, we first discuss the energy consumption by transportation (current and projected) and then we proceed to the next chapter by presenting and discussing the status of transportation emissions. In Chapter 3 we focus on social and environmental problems induced by transportation (at the local and the global scale). In Chapter 4 we discuss the mitigation actions implemented so far and conclude with a short commentary on the future potential.

3.13.2 Energy Consumption by Transportation

Forecasts for the world population indicate that it will exceed 9 billion people in 2050 (UN 2011). The largest percentage of this growth is taking place in the developing world combined with an increased urbanization and demand for energy and transportation. No one knows how long the world's oil reserves will last, but even the oil industry suspects the world oil peak is now approaching. The extent to which conventional nonrenewable fossil fuels will continue to be the primary resources for nearly all transportation fuels is subject to debate. Some studies estimate global resources for oil at about a trillion barrels. This represents 30 years of reserves at the present rate of consumption (Rodrigue et al. 2009). According to BP (BP 2011b), proved oil reserves in 2010 were sufficient to meet 46.2 years of global production. But the gap between demand and supply is narrowing, an effect compounded by the peaking off of global oil production. The steady surge in demand from emerging economies requires a significant additional output. This raises concern about the capacity of major oil producers to meet this rising world demand. The producers are not running out of oil, but the existing reservoirs may not be capable of producing on a daily basis the increasing volumes of oil that the world requires.

World liquids production in 2035 will exceed the 2008 level by 26.6 million barrels per day, with production increases expected for both Organization of the Petroleum Exporting Countries (OPEC) and non-OPEC producers (**Figure 1**). Overall, 57% of the total increase is expected to come from non-OPEC areas, including 31% from non-OPEC unconventional liquids production alone. OPEC will produce 46.9 million barrels per day in 2035, and non-OPEC producers will provide 65.3 million barrels per day. Increasing volumes of conventional liquids (crude oil and lease condensate, natural gas plant liquids and refinery gain) from OPEC members contribute 10.3 million barrels per day to the total increase in world liquids production from 2008 to 2035, and conventional liquids supplied from non-OPEC nations contribute 7.1 million barrels per day. Unconventional liquids production increases by about 5% annually on average over the projection period, because sustained high oil prices make unconventional liquids more competitive, and 'above-ground' factors ('Above-ground' factors refer to those nongeological factors that could affect supply, including but not limited to government policies that limit access to resources; conflict; terrorist activity; lack of technological advances or access to technology; price constraints on the economic development of resources; labor shortages; materials shortages; weather; environmental protection actions; and short- and long-term geopolitical considerations (USEIA, 2011)) limit the production of economically competitive conventional liquids. Unconventional fuels account for 35% (9.2 million barrels per day) of the increase in total liquids production in the US Energy

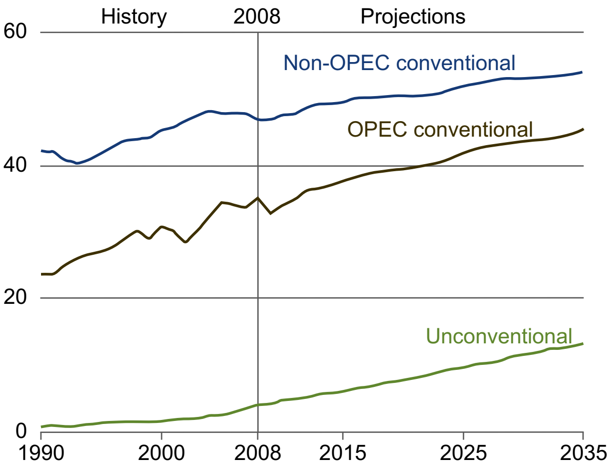

Figure 1 World total liquid fuels production for the period 1990–2035 (million barrels per day). Source: US Energy Information Administration (USEIA), International Energy Outlook 2011 (IEO2011). [Available online at http://www.eia.gov/forecasts/ieo/world.cfm.] Assessed at 02/02/2012.

Information Administration (USEIA 2012) reference case, and 8.2 million barrels per day of the increase in unconventional supply comes from non-OPEC sources.

Transportation consumes more than 50% of world of liquid fuels and its share tends to increase in the future (Hirsch et al. 2005). Estimations say that growth in transportation energy use from 2008 to 2035 will account for 87% of the total increase in world liquid fuels consumption (Figure 2). Most of the growth is expected among the developing non-OECD (Organization for Economic Co-operation and Development) nations, whereas consumption among the developed OECD nations is projected to remain relatively flat or decline. In 2008, non-OECD countries as a group consumed 34% less energy for transportation than OECD countries. In 2035, non-OECD energy use for transportation will probably exceed that in the OECD countries by 19% (Table 1).

The relationship between transportation and energy is a direct one, but subject to different interpretations because it concerns different transport modes, each having a specific performance level (Rodrigue et al. 2009). There is often a compromise between speed and energy consumption, related to the desired economic returns (Figure 3). Passengers and high-value goods can be transported by rapid but energy-intensive modes because the time component of their mobility tends to have a high value, which conveys the willingness to use more energy. Economies of scale, mainly those achieved by maritime transportation, are linked to low levels of energy consumption per unit of mass being transported, but at a lower speed. This fits relatively well with freight transport imperatives, particularly bulk. Comparatively, air freight has high energy consumption levels linked to high-speed services.

Energy use in the transportation sector includes energy consumed in moving on land (road, rail, pipelines), water (maritime), and air (aviation). Each of the transportation components is characterized by specific characteristics (Rodrigue et al. 2009):

- Land transportation accounts for the great majority of energy consumption – about 85% of the total energy used by the transport sector in developed countries. This trend is not, however, uniform within the land transportation sector itself, because road transportation is almost the sole mode responsible for additional energy demands over the last 25 years. Despite a falling market share, rail transport, on the basis of 1 kg of oil equivalent, remains four times more efficient for passengers and twice as efficient for freight movement than road transport. Rail transport accounts for 6% of global transport energy demand.

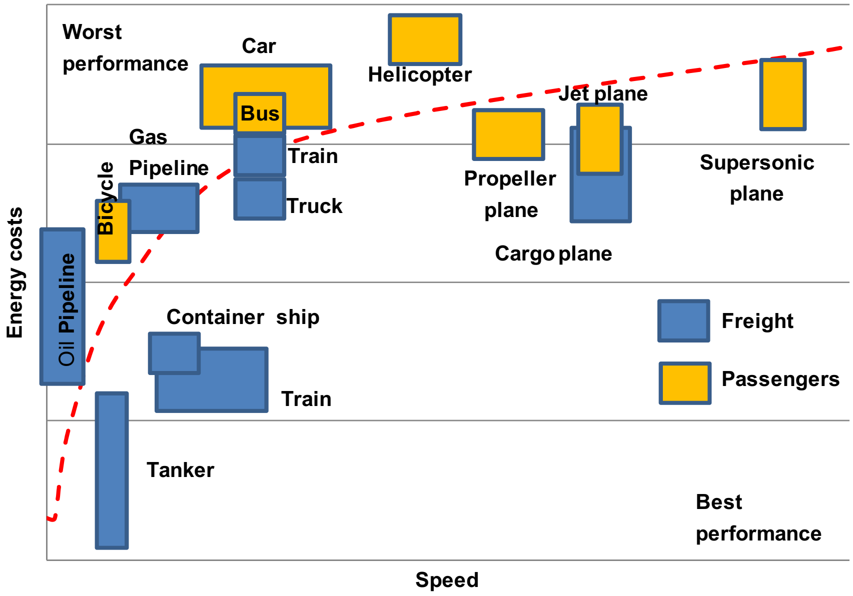

Figure 3 Transportation modes and energy. Source: Rodrigue, J.-P., C. Comtois, and B. Slack, 2009: *The Geography of Transport System.* 2nd ed. Routledge, New York.

- Maritime transportation accounts for 90% of cross-border world trade as measured by volume. The nature of water transport and its economies of scale make it the most energy efficient mode because it uses only 7% of all the energy consumed by transport activities, a figure way below its contribution to the mobility of goods.
- Air transportation accounts for 8% of the energy consumed by transportation. Air transport has high energy consumption levels, linked to high speeds. Fuel is the second most important budget for the air transport industry, accounting for 13–20% of total expenses. This accounts for about 1.2 million barrels per day. Technological innovations, such as more efficient engines and better aerodynamics, have led to a continuous improvement of the energy efficiency of each new generation of aircrafts.

All those listed, almost entirely, rely on oil. The only exception to this is electric rail transport, which uses for a considerable share other energy sources, like hydro or nuclear power, depending on the energy mix in electricity generation. As is clearly shown in various future projections, energy use by every transport mode is expected to keep on growing at a similar rate as in the last decades of twentieth century and to double between 2000 and 2040 (Figure 4).

A primary factor in the projected increase of energy demand for transportation is the steadily rising demand for personal travel in both the developing and mature economies. In the developing economies, with gains in urbanization and personal incomes, demand for air travel and motorized personal vehicles increases. World vehicle ownership is projected to grow rapidly – by 60% from around 1 billion today to 1.6 billion by 2030 (Figure 5), particularly in the non-OECD countries in which the vehicle population will rise from 340 million to 840 million over the next 20 years. In the industrialized OECD countries, growth in vehicle ownership

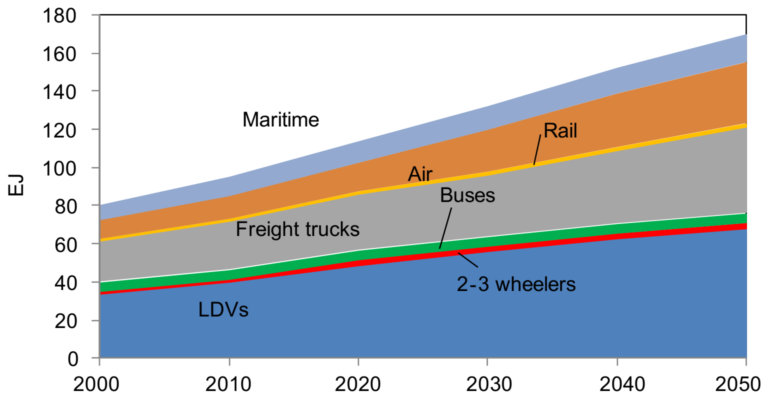

Figure 4 Projection of transport energy consumption by mode for the period 2000–50. Source: IPCC, 2007: Summary for policy makers. *Climate Change 2007: The Physical Basis. Contribution of Working Group I to the Fourth Assessment Report of the Intergovernmental Panel on Climate Change*, S. Solomon, et al., Eds., Cambridge University Press, Cambridge.

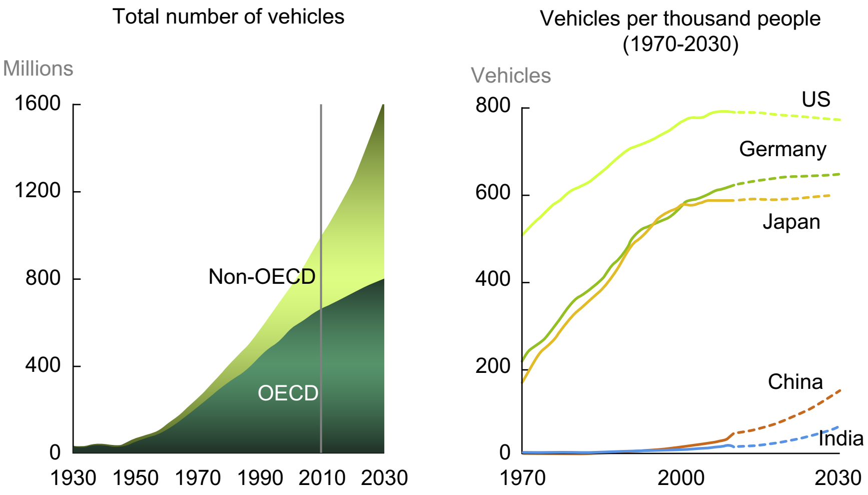

Figure 5 World vehicle population for the period 1930–2030 and vehicle density for the period 1970–2030. Source: BP Energy Outlook 2030, London, January 2011a. [Available on line at http://www.bp.com/liveassets/bp_internet/globalbp/globalbp_uk_english/reports_and_publications/statistical_energy_review_2011/STAGING/local_assets/pdf/2030_energy_outlook_booklet.pdf.] Assessed at 18/11/2011.

per capita slows as saturation levels begin to be reached. In most of the non-OECD countries, growth in vehicle ownership is expected to continue at a rapid pace. With higher economic growth rates and higher energy intensities, the non-OECD countries' share of world transportation energy demand rises from 40% in 2008 to 54% in 2035. In addition, strong GDP growth in the non-OECD economies leads to modal shifts in the transport of goods, and freight transportation by trucks leads the growth in non-OECD demand for transportation fuels.

3.13.3 Air Pollution and Climate

Current transport patterns, based primarily on private motorized vehicles, generate many social, environmental, and economic costs, accounting for more than half of global liquid fossil fuel consumption and nearly a quarter of the world's energy-related carbon dioxide (CO_2) emissions (IEA 2009). Transport is also typically responsible for around 80% of developing cities' local air pollution and more than 1.3 million fatal traffic accidents worldwide, most of which occur in developing countries (WHO 2009). Furthermore, the chronic traffic congestion caused by excessive motorization leads to lower productivity and reduced levels of accessibility in many of the world's urban areas. These patterns of transportation are expected to worsen under the continuous and rapid trend of motorization. There is a growing consensus by experts, policy makers, and the general public that these trends cannot continue without seriously affecting the economic viability and environmental quality of their cities and countries.

Emissions from energy and transportation systems are known to affect air quality, including photochemical smog, urban and regional haze, fine aerosol impacts on lung function, acid rain and acid deposition, greenhouse gas and aerosol impacts on climate, as well as stratospheric ozone depletion. Hence, the main socioenvironmental problems related with the consumption of petroleum fuels for transportation can be viewed at two scales:

1. The local scale: air pollution from vehicle exhausts that is harmful to human health, animals, and vegetation and,
2. The global scale: GHG emissions, mostly in the form of carbon dioxide (CO_2), that contribute to the earth's climate.

3.13.3.1 Air Pollution

3.13.3.1.1 Land Transportation

In most urban areas, emissions from increasing numbers of automobiles are a major contributor of harmful pollutants. Harmful primary pollutants are particulate matter (PM), carbon monoxide (CO), nitrogen oxides (NO_x), and non methane volatile organic compounds (NMVOCs) such as benzene and polycyclic aromatic hydrocarbons (PAHs). Sulfur dioxide and lead emissions from land transport have been strongly reduced and are now less relevant, at least in the developed world. Secondary traffic-related pollutants that often can extend from the local to the regional scale include gases such as ozone (O_3), peroxyacetyl nitrate (PAN), formaldehyde (HCHO), and secondary particles consisting of sulfate and nitrate organic compounds.

Road transport accounted for 22.5% and 21.2% of total global NO_x and PM emissions, respectively, in 2000 (Broken et al. 2007). **Figure 6** compares the worldwide evolution and trends of NO_x and PM emissions of road transport with those of all sources together (Metz 2005). Global emissions of NO_x and PM from road vehicles are projected to decrease by 65 and 53%, respectively, from 2010 to 2050 (significantly higher reductions from those corresponding to all sources emissions – 41% and 43% for NO_x and PM, respectively). These reductions are basically induced by considerable improvements in emissions factors; Takeshita (2011) reports over the same period reductions of 87% (NO*x*) and 91% (PM) (**Figure 7a-c**). Projections over shorter periods (2020) indicate that PM emissions reduction from road transportation will probably be masked by the increasing share of nonexhaust sources to the total emissions (Kousoulidou et al. 2008). However, despite the enormous technological progress made and optimistically projected, the continued growth in the number of vehicles and kilometers traveled as well as the existence of old and malfunctioning vehicles, make air pollution by motor vehicles a serious health concern, especially in the megacities of emerging economies (Baidya and Borken-Kleefeld 2009).

The railway sector emits significant amounts of NO_x (when compared with its share in the total energy use, in particular) as well as PM. As a result, emission standards that apply to all new and remanufactured locomotives have been established in both the United States and European Union (U.S. Department of Energy 2002). Exhaust aftertreatment devices for the reduction of NO_x (selective catalytic reduction, NO_x adsorber catalysts) and PM (catalyzed diesel particulate filters (CDPF)) have not been implemented in locomotive engine applications, but they may be necessary to meet future emission regulations. The railroad industry probably will be able to meet its near-term emissions regulations without resorting to aftertreatment devices, whereas the trucking industry required the devices earlier. Although the unique characteristics of locomotives may prevent direct transfer of the technologies developed for trucks, much can be learned from that industry.

Road traffic emissions comprise not only tailpipe exhaust emissions but also non exhaust emissions derived mostly from the vehicle-induced resuspension of dust deposited on the road and in part from the direct emissions from vehicle wear (brakes, tires, etc) (Thorpe and Harrison 2008). Non exhaust emissions are often of the same order or even greater than exhaust emissions, especially when rainfall rates are low and the wash-off of the road is reduced. Despite the high environmental and health burden of nonexhaust sources in urban environments, their emissions are often unknown and still uncontrolled. Because technological improvement will typically only affect 'tailpipe' emissions, the estimation of the nonexhaust part becomes increasingly relevant.

3.13.3.1.2 Maritime Transportation

Maritime is a very fuel efficient mode of transportation and is generally regarded as an environmentally friendly mode of transport. For some gases (i.e., SO_x), however, this mode causes more emissions per ton kilometer than other modes of transport (Eyring et al. 2010). Emissions from maritime transportation cannot be directly compared to emissions over land or within cities. The impact of emissions depends in part on where they take place and on where emissions are deposited. One argument is that they take place at sea and that their impact on air quality over land and within cities is negligible. However, this argument is not generally valid. About 70% of the emissions from oceangoing shipping occur within 400 km of the coastlines along the main trade routes (Corbett et al.1999). Moreover, a substantial part of maritime emissions takes place during operation within port. Ship maneuvering in harbors contributes about 6% of NO_x and 10% of SO_2 to total shipping emissions (Corbett and Fischbeck 1997). Besides maneuvering, loading and unloading of tankers also contribute substantially to harbor emissions because this is a highly energy consuming process (Wismann and Oxbol 2005). The harbor emissions often occur near major residential areas and can be transported far inland owing to local land–sea breeze winds. Thereby, ship emissions can have an impact on the air quality in coastal regions and may partly offset the decline of land-based sources and coastal pollution due to national control measures (Schlager and Pacyna 2004). On the global scale these effects are small, but could be more significant in shallower coastal waters where shipping is concentrated. **Figure 8** shows possible range of future NO_x, PM, and SO_x (a significant emission of maritime transportation due to high sulfur content of marine diesel) emissions according to four different technology scenarios and four different ship traffic demand scenarios (Eyring et al. 2005). The scenarios are based on assumptions on future ship traffic demand and technological improvements. The four future ship traffic demand scenarios are mainly determined by economic growth, which follows the IPCC Special Report Emission Scenarios storylines (IPCC 2009).

Inland shipping, that is, shipping on rivers and lakes, is not important in terms of emissions at the global scale. Emission estimates are not always comparable in different studies because the differentiation between ocean-going ships and inland shipping is not always sharp (Uherek et al. 2010). It is estimated that they are significantly less than road and air transport and comparable to those of rail transport (Ebert 2005).

3.13.3.1.3 Air Transportation

Air transport affects air quality in several ways. Its impact can be divided into the effects of aircraft emissions, which represent the major contributor to aviation-derived air pollution, and the lesser but nonetheless significant air pollution that occurs due to the operation of airports and their ancillary services. The impact of air transport on air quality is divided into direct and indirect effects (Daley 2010). Direct effects include emissions of air pollutants directly into the atmosphere, especially of NO_x and PM. In contrast, indirect effects occur when aircraft emissions initiate other physical or chemical processes that in turn cause air pollution, as when tropospheric ozone (O_3) is formed as a side-effect of NO_x emissions from aircraft and other airport-related sources.

NO_x emissions can be reduced by careful combustor design (Lee 2009), because of the fact that NO_x production tends to increase as an unintended consequence of the drive to achieve greater fuel efficiency; absolute NO_x emissions from aircraft are forecast to increase by a factor of approximately 1.6 between 2002 and 2025 (Daley 2010). These emissions are most concentrated in the vicinity of the runways, taxiways, and aprons of airports, as well as close to major roads. Recent work has demonstrated that exhaust pollutants may be transported to the ground far more effectively by aircraft wakes than by ambient atmospheric dispersion alone (Schürmann et al. 2007). Scientific assessments of PM emissions from aviation sources are characterized by greater uncertainty than are those of NO_x emissions; however, the contribution of airport sources to ambient concentrations of PM in areas adjacent to airports tends to be smaller than that of airport-derived NO_x (Daley 2010). The highest concentrations of aviation derived PM occur close to runways, taxiways, aprons and major roads; furthermore, as with NO_x, particles can be very effectively transported to the surface by aircraft wakes. PM emissions are forecast to increase over the period 2002–25 because of the difficulty of sustaining significant technology improvements in this area, meaning that aviation-derived particles are likely to remain an air pollutant of critical concern over the decadal timescale. **Figure 9** compares transportation related global annual emissions of NO_x, SO_2, and PM for the year 2000.

3.13.3.2 GHG Emissions

The primary GHGs produced by the transportation sector are CO_2, methane (CH_4), nitrous oxide (N_2O), hydrofluorocarbons (HFCs), and chlorofluorocarbons (CFCs). Water emissions at the Earth's surface have no climate effect. If released at cruise altitude by commercial aircraft, however, water vapor emissions can be more significant.

Globally, CO_2 accounts for 95% of transportation GHGs. HFCs, which are used in automobile, truck, and rail air conditioning and refrigeration systems, account for another 3% of transportation GHG emissions. N_2O and CH_4, which are both emitted as byproducts of combustion, account for the remainder of the transportation GHG emissions inventory. These emissions are all well-mixed in the atmosphere and long-lived, lasting from years to many decades. The long residence time requires that the historical development of emissions is taken into account when calculating the contribution to GHG enhancement and thus the radiative forcing at a given point in time. According to the World Energy Outlook 2009 (IEA 2009), global energy-related annual CO_2 emissions could increase to over 40 Gt by 2030 and transport emissions would make up over one fifth of that despite significant mitigation policies built into the reference scenario (**Figure 10**).

3.13.3.2.1 Land Transportation

Land transportation is, second to power generation, the largest emitter of CO_2 globally covering around 23% of the global total emissions in 2009 and the emissions are rising within the

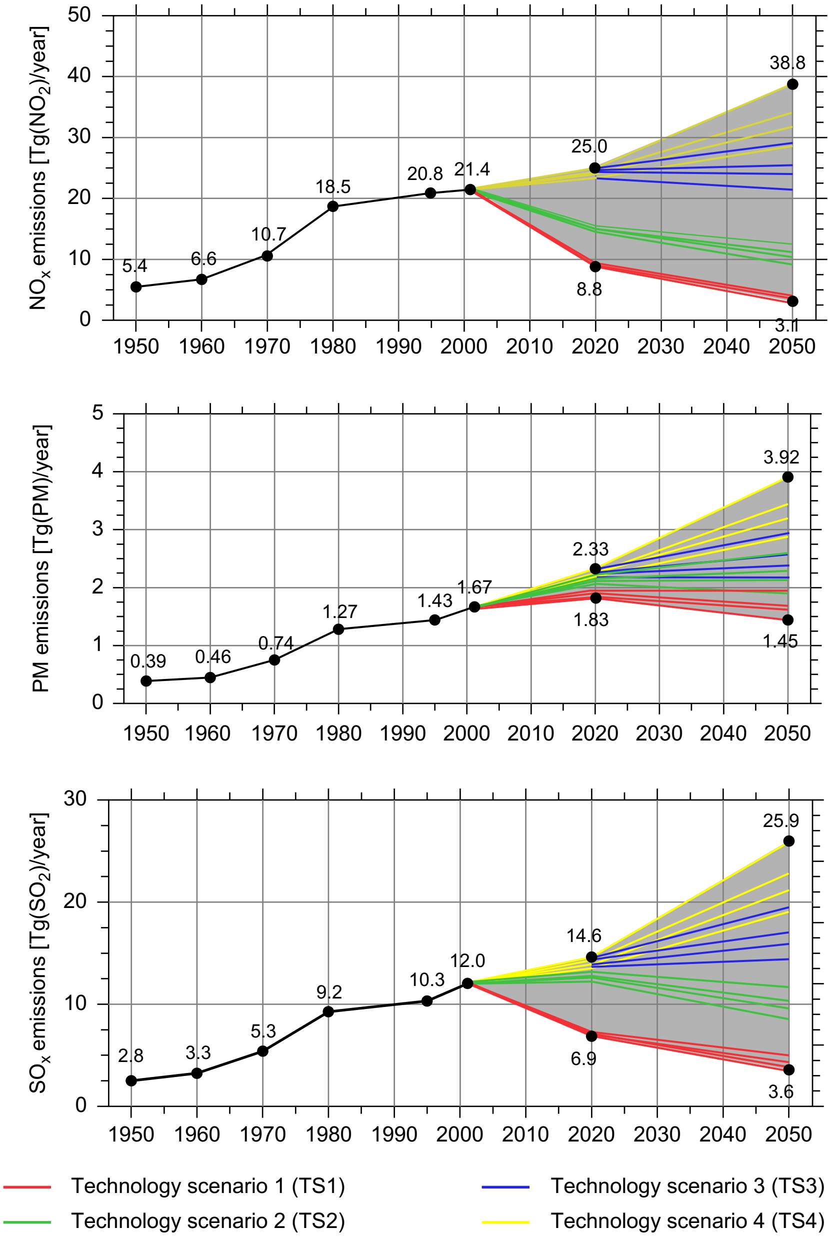

Figure 8 Possible range of future NO$_x$, PM, and SO$_x$ maritime missions according to four different technology scenarios (TSs) and four different ship traffic demand scenarios (DSs). Source: Eyring, V., H. W. Köhler, A. Lauer, and B. Lemper, 2005: Emissions from international shipping: 2. Impact of future technologies on scenarios until 2050. *J. Geophys. Res.*, **110,** D17306.

entire period 1990–2009 (with a small decrease of 1.7% in 2008) (Olivier et al. 2011). (Other sources include industrial processes, agricultural processes, fossil fuel retrieval, processing and distribution, residential and commercial sources, land use and biomass burning, waste disposal and treatment.) Land transportation accounted for 4.58 Gt (1990) and 6.54 Gt (2009), representing an increase of approximately 43% (Figure 11). Within road transport, automobiles and light trucks produce well over 60% of emissions, but in low- and middle-income developing countries, freight trucks (and in some cases even buses) consume more fuel and emit more CO$_2$ than the automobiles and light trucks.

Although there is yet no global-gridded rail inventory available, this sector is certainly the lowest CO$_2$ emitter (in terms of 'tailpipe' emissions at least) because it has been to a large extent electrified (in Europe, for example, diesel-powered vehicles currently account for around 20% of operations (UIC 2010)). Available studies show that rail emissions make up only 1–3% of the total transportation emissions (EEA 2003; AAR 2011).

3.13.3.2.2 Marine Transportation

Estimates for the global CO$_2$ emissions for maritime differ substantially depending on the approach (bunker fuel statistics

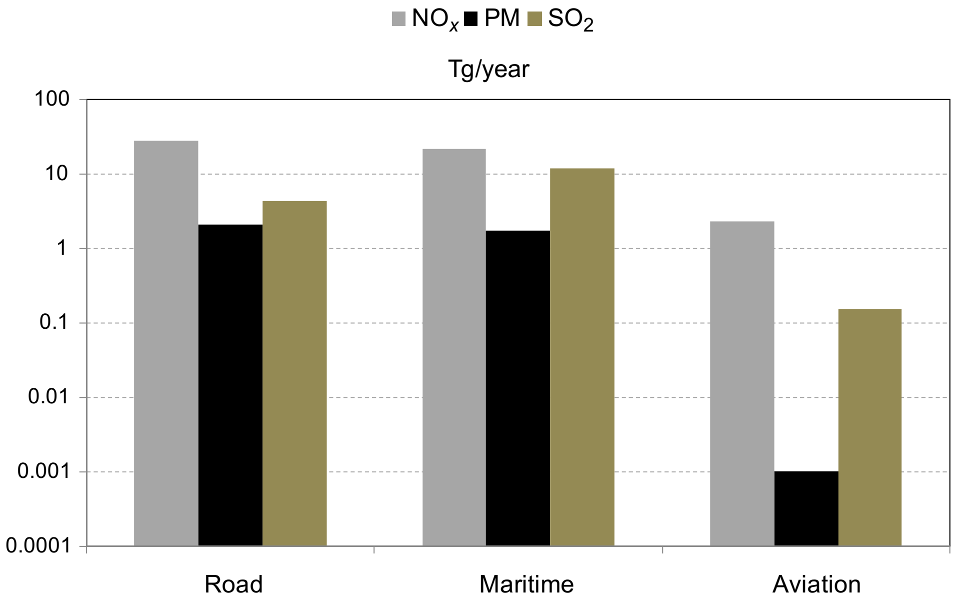

Figure 9 Transportation-related gobal annual emissions of NO$_x$, SO$_2$, and PM estimated for the year 2000.

or activity based figures). For year 2000 for example, estimates range from 501 to 960 Tg (Eyring et al. 2010). Recent studies reveal converging estimates of current ship emissions and suggest that oceangoing ships emitted around 800 Tg CO$_2$, contributing around 2.7% to all anthropogenic CO$_2$ emissions in 2000 (Eyring et al. 2010). Figure 12 shows possible range of future CO$_2$ emissions according to four different technology scenarios and four different ship traffic demands.

Emission equivalent of CFCs from the world shipping fleet is very uncertain and it has been estimated (on annual global emissions) from around 1–3% to 10% for the year 1990 and data have not been renewed (Eyring et al. 2010).

3.13.3.2.3 Air Transportation

Air transport is currently a small but nonetheless significant contributor to climate, mainly as a result of the various, interrelated effects of aircraft emissions. However, given the projected sustained rapid growth of the air transport industry of around 5% per year, aircraft emissions are expected to constitute a substantial proportion of global greenhouse gas emissions by 2050 (Bows et al. 2009). Global aviation CO_2 emissions in 2005 were estimated to be 733 Tg, which constituted roughly 2–2.5% of total anthropogenic CO_2 emissions (Lee et al. 2010). By 2050, in the worst case scenarios, those emissions are projected to have grown by a factor of three over 1992 levels (Figure 13). Under this pressure, aircraft manufacturers are constantly seeking to improve the efficiency of airplanes and engines. These efforts include improvements of existing designs, new configuration concepts, and new roles and requirements.

A further complication is the climate impact of NO_x emissions, because they cause changes in the concentration of other greenhouse gases. These changes partly offset each other, and their impacts are regional and thus not strictly additive. Overall, however, the combined impacts of the various consequences of commercial aircraft are estimated to be larger than the impacts of the CO_2 emissions alone (Schäfer et al. 2009).

Although CO_2 accounts for the majority of observed effects, human activities produce short-lived and spatially variable emissions that may also have a significant warming effect. Two substances closely associated with the transportation sector are

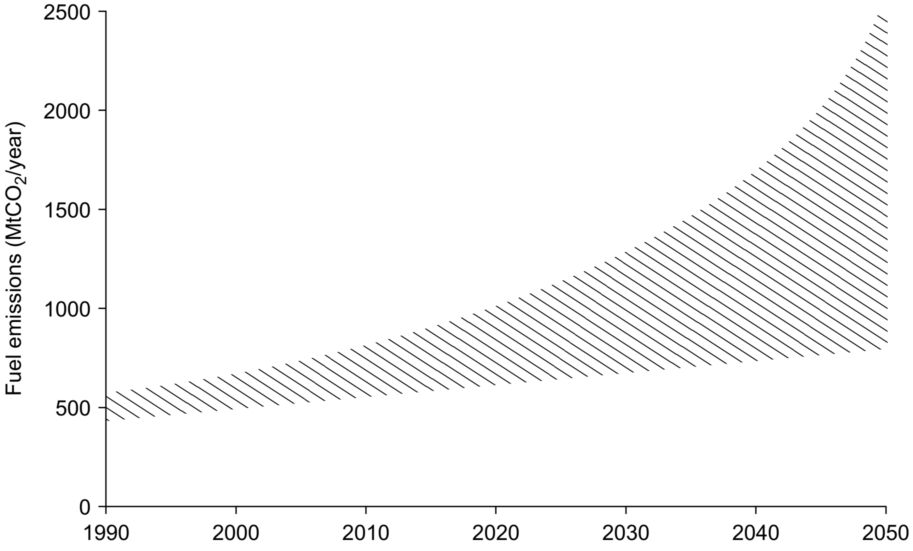

Figure 13 Global CO_2 emissions from aviation under various scenarios, 1990–2050. Source: Lee, D.S., and Coauthors, 2010: Transport impacts on atmosphere and climate: Aviation. *Atmos. Environ.*, **44,** 4678–4734.

tropospheric ozone and black carbon. Because of their short atmospheric lifetime – which ranges from weeks to months – and uncertainties about their warming potential, tropospheric ozone and black carbon are currently not included in official emissions estimates. Tropospheric ozone is estimated to have the third largest increase in radiative forcing since the preindustrial era, behind CO_2 and CH_4 (EPA 2009). It is produced when precursors such as NO_x, CO, and NMVOCs react with sunlight in the atmosphere. Motor vehicle exhaust accounts for a majority of NO_x and CO emissions, and is also the largest source of NMVOCs. Black carbon is an aerosol that causes warming by both absorbing solar radiation in the atmosphere and by reducing the reflectivity of snow and ice. The net impact of these two warming effects is estimated to be slightly lower than that of ozone, albeit with a higher degree of uncertainty. Black carbon is a component of the PM emitted from incomplete combustion processes, especially the burning of diesel fuel. Transportation is estimated to account for about one fifth of black carbon emissions (Bond et al. 2004). Unlike CO_2 emissions, ozone precursors and black carbon can be restricted by emissions controls. Both have been significantly reduced by earlier control technologies and are expected to be further reduced. Given the short lifespan of black carbon and ozone precursors, reducing their respective emissions would reduce warming within weeks to months (Unger et al. 2009).

3.13.3.3 Indirect Emissions

Indirect emissions are related to economic and industrial processes sustaining the transport system (production of fuels, vehicles and construction materials). They all have a life cycle timing their production, utilization, and disposal. Thus, the evaluation of the transport–environment link without the consideration of cycles in the environment and in the product life is likely to convey a limited overview of the situation and may even lead to incorrect appraisal and policies. At present, however, estimations have high uncertainties and should be taken into account critically. Figure 14 shows estimations for GHG emissions per passenger kilometer traveled of several vehicles. The differences of urban diesel bus estimated for two different traffic modes (peak vs. off peak) indicate the significance of the issue.

3.13.3.4 Impacts

3.13.3.4.1 On Health

The concern regarding emissions is the detrimental impact these may have on human health. We will not discuss road accidents, effects on physical activities and urban landscape, traffic congestion, and noise pollution (although their significance should be noted); instead, we will focus on the dimension for which ample evidence has been gathered through numerous studies since the late 1980s. According to WHO estimates, more than 2 million premature deaths each year are attributed to urban outdoor air pollution as well as indoor air pollution from the combustion of solid fuels. More than half of them occur in developing countries (WHO 2005). For the most part, these emissions have potential impacts on the human respiratory system, ranging from difficulty in breathing to death.

The effects of transport-related pollution on the urban scale concern air quality and health impacts due to particles, their toxic components, and toxic short-lived gases (Uherek et al. 2010). The most significant pollutant in terms of health is PM. The health effects of PM are strongly linked to particle size. Small particles, such as those from fossil fuel combustion, are likely to be most dangerous, because they can be inhaled deeply into the lungs, settling in areas where the body's natural clearance mechanisms cannot remove them. The constituents in small particulates also tend to be more chemically active and may be acidic as well and therefore more damaging (WHO 1994). Short-term increases in PM

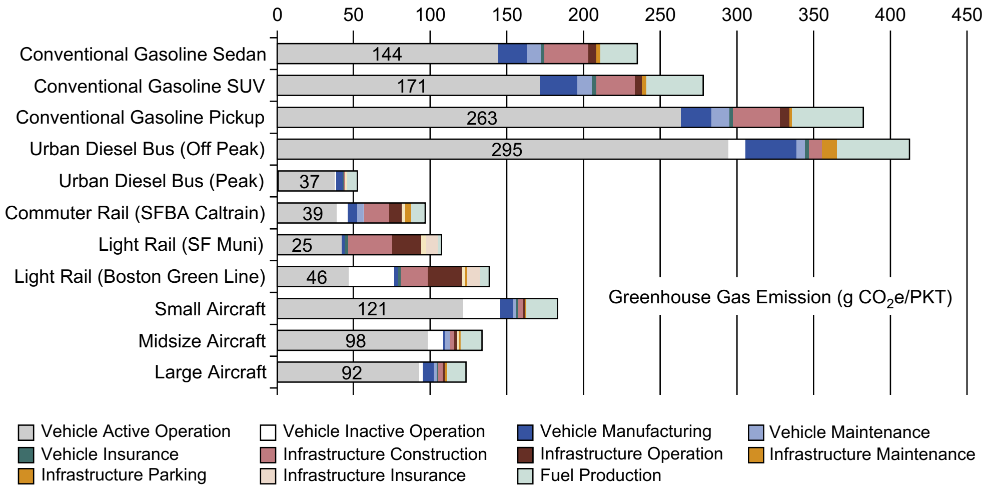

Figure 14 GHG emissions per passenger kilometer traveled (PKT) of several vehicles. Source: Chester, M.V., and A. Horvath, 2009: Environmental assessment of passenger transportation should include infrastructure and supply chains. *Environ. Res. Lett.*, **4**, (2), 1–8. Adapted from Uherek, E., and Coauthors, 2010: Transport impacts on atmosphere and climate: land transport. *Atmos. Environ.*, **44,** 4772–4816.

lead to increased mortality, increased admissions to hospital for respiratory and cardiovascular diseases, increased frequency of respiratory symptoms and use of medication by people with asthma, and reduced lung function (WHO 1994). More demonstrative and sometimes controversial evidence comes from a number of epidemiological studies which have linked short-term increases in PM levels, such as the ones that occur during pollution episodes, with immediate (within 24 h) increases in mortality. This pollution-induced spike in the death rate ranges from 2% to 8% for every 50 $\mu g\, m^{-3}$ increase in particulate levels. These basic findings have been replicated on several continents, in cities as widely divergent as Athens, Sao Paulo, Beijing, and Philadelphia (Shprentz 1996; HEI 1995; Ostro 1993). These estimates should be viewed with caution, however, because some of those who die during a pollution episode were already sick, and the pollution may have hastened the death by only a few days. The association of PM with health effects has been determined in environments with complex mixtures of highly correlated pollutants, making it difficult to disentangle individual effects. The effects attributed to PM could therefore be interpreted as indicating the effects of the pollutant mixture as a whole. The evidence on the health effects of O_3 and nitrogen dioxide (NO_2) and other pollutants resulting directly from the combustion of fossil fuels is similarly unclear. The effects may actually represent the impact of fine particles that are not usually monitored. The estimates of health impact for each pollutant should therefore take account for the complexity of the situation (Anenberg et al. 2010). Relative risks have been summarized indicating PM2.5 as the most dangerous pollutant (Figure 15). Studies conducted in Europe further emphasize this observation (Boldo et al. 2006).

3.13.3.4.2 On the Planet

At the second decade of 21st century, the world is faced with many challenges including volcanic activity, flooding, drought, fire and hurricanes. Much of the world's population is located in areas that are susceptible to flooding, while 20 of the 30 megacities of world (population greater than 10 million) are located near sea level.

The main impact of GHG emissions from the burning of fossil fuels on the planet is, as their name indicates, the 'Greenhouse Effect' that exacerbates the earth's natural greenhouse effect. The greenhouse effect is driven via infrared radiation. GHGs trap some of the infrared radiation that escapes from the earth, which makes/keeps the earth warmer than it would otherwise be. GHG act as a 'blanket' for this infrared radiation and keep the earth's lower layers of the atmosphere warmer and the upper layers cooler, than it would otherwise be if the GHGs were not there. This is accepted as a fact by almost all researchers, and serious doubting starts from this point.

A possible impact may result from the possible sea-level change. In some cases this would simply result in the inundation of low-lying areas around the world's oceans. This would not occur overnight, and there would be more than enough time for individuals in these areas to move to higher ground. On the other hand, complacency could create a disaster in the wake of sea-level surge events. These are, for example, the large

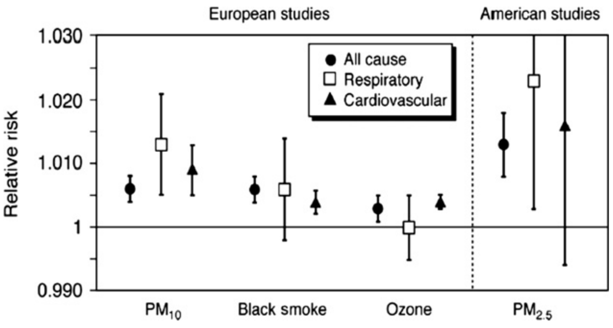

Figure 15 Summary estimates for relative risks (RR) for mortality and different air pollutants. Source: Uherek, E., and Coauthors, 2010: Transport impacts on atmosphere and climate: land transport. *Atmos. Environ.*, **44,** 4772–4816.

waves created by storms that usually come crashing ashore as part of a hurricane or typhoon.

One of the many negative outcomes to the planet is the acidification of the earth's oceans. Ocean acidification is the changing of the planet's oceans pH levels from alkaline to acid. The oceans absorb about 25% of the CO_2 emissions from the planet's atmosphere. This helps offset or mitigate possible effects on climate. When CO_2 is absorbed by the oceans, it dissolves in the seawater and carbonic acid is formed. Carbon emissions have lowered the pH of the oceans by approximately 10% since the advent of the industrial revolution. Ocean acidification decreases the ability of marine organisms such as phytoplankton and algae to function. Ocean acidification has also been linked to the dying off of coral reefs, as well as negatively impacting fish populations.

Other impacts include (Rodrigue et al. 2009):

Water quality. Transport activities have an impact on hydrological conditions. Fuel, chemical and other hazardous particulates discarded from aircraft, cars, trucks, and trains or from port and airport terminal operations, such as deicing, can contaminate rivers, lakes, wetlands, and oceans. Because demand for shipping services is increasing, marine transport emissions represent the most important segment of water quality inventory of the transportation sector. The main effects of marine transport operations on water quality predominantly arise from dredging, waste, ballast waters, and oil spills. Major oil spills from oil cargo vessel accidents are one of the most serious problems of pollution from maritime transport activities.

Soil quality. The environmental impact of transportation on soil consists of soil erosion and soil contamination. Coastal transport facilities have significant impacts on soil erosion. Soil contamination can occur through the use of toxic materials by the transport industry. Fuel and oil spills from motor vehicles are washed on road sides and enter the soil. Chemicals used for the preservation of railroad ties may enter into the soil. Hazardous materials and heavy metals have been found in areas contiguous to railroads, ports, and airports.

Biodiversity. Transportation also influences natural vegetation. The need for construction materials and the development of land-based transportation has led to deforestation. Many transport routes have required draining land, thus reducing wetland areas and driving-out water plant species. The need to maintain road and rail rights-of-way or to stabilize slopes along transport facilities has resulted in restricting growth of certain plants or has produced changes in plants with the introduction of new species different from those which originally grew in the areas. Many animal species are becoming extinct as a result of changes in their natural habitats and reduction of ranges.

In reverse, all the above will effect transportation itself. The effects derive from possible (1) temperature and precipitation changes, (2) water- and sea-level change, and (3) abatement activities (Black 2010) and include

- flooding of streets and highways and damage to transport infrastructure during storm events;
- changes to the port terminal facilities, increase of inland navigability and channelization;
- permanently frozen ground in north areas and flooding of at-grade and subway rail transit systems in metropolitan areas;
- flooding of airports located in coastal areas, airports reconstruction, and issues related to the safe and efficient operation of aircraft. Changes in wind direction and strength related to atmospheric conditions could be of concern in the future. Air temperature can impact flights if, when the temperature exceeds a certain threshold level, air density becomes too low to allow the aircraft to gain lift.

3.13.4 Mitigation Actions

Reactions against the above impacts are taking place on three levels:

1. Political–social
2. Science/technological
3. Legislation

Nevertheless, it should be remembered that the nature and extent of transportation problems vary from one country to another. Although most developed nations have taken strong action to control urban pollution, this is not the case for developing countries, wherein the concentration of wealth among the economic and political elite has distorted transport policies. A disproportionate share of funds is spent facilitating the ownership and use of private cars, while the needs of mostly low-income bus riders, pedestrians, and cyclists are ignored.

Below we focus on measures/actions taken to reduce urban air pollution and GHG emissions and on possible future pathways.

3.13.4.1 Urban Air Pollution

Although aviation (airport/near airport) air pollution may be important for local environment it is not regulated. Maritime pollution control began recently in European Union (EU) by limiting the sulfur content to 0.1% in marine fuels for harbor regions in 2010 and the United States adopted emissions standards for NO_x, CO, and HC for all US ships with engines manufactured after January 2004 and recently issued plans for new emission standards for diesel engines onboard large oceangoing vessels (Eyring et al. 2010). Hence, the discussion will focus on road transportation pollution.

In the early 1960s, where eye irritation was first reported in Los Angeles County, a typical car (without pollution control devices) emitted about $48\,\mathrm{g\,km^{-1}}$ CO, $14.5\,\mathrm{g\,km^{-1}}$ hydrocarbons (HCs), and $2.55\,\mathrm{g\,km^{-1}}\,NO_x$. After the pioneering chemistry research of A.J. Haagen-Smit and other scientists at the California Institute of Technology, it was found that NO_x and HCs exposed to sunlight produced secondary pollutants (photochemical smog) that caused eye and throat irritations and reduced visibility. Further studies indicated that the complex and various pollutants existing in automobile emissions came from four sources: engine exhaust, crankcase blowby, carburetor, and fuel tank. These investigations were central to the development of various emissions-control technologies (Krier and Ursin 1977). Since then, emissions regulations and the usage of emissions reduction technologies have evolved at different rates throughout the world. Generally, the US and western European countries have been forerunners in these areas.

In the United States, the Clean Air Act of 1970 granted the Environmental Protection Agency (EPA) authority to regulate motor vehicle pollution, and the Agency's emission control policies have become progressively more stringent since the act's inception. EPA standards dictate how much pollution vehicles may emit, but manufactures decide how to achieve compliance with the agency's standards. Emissions reductions in the early 1970s occurred primarily because of fundamental improvements in engine design, the addition of charcoal canisters to collect hydrocarbon vapors, and the installation of exhaust gas recirculation valves to reduce nitrogen oxides.

The advent of (two-way) catalytic conversion technology in 1975 significantly reduced hydrocarbon and carbon monoxide emissions. The use of catalytic converters also provided an enormous ancillary environmental benefit. Because lead contained in fuel irreversibly damages catalysts, the widespread introduction of unleaded gasoline was initiated in 1975. The subsequent elimination of lead from gasoline resulted in dramatic reductions in ambient lead levels and alleviated many lead-related environmental and human health effects.

The next major milestone in vehicle emission control technology came in 1980–81. These years witnessed the introduction of one of the most commonly used emissions systems for gasoline powered vehicles – one that falls into the exhaust gas aftertreatment category – the 'Three-Way Catalyst.' These systems convert carbon monoxide and hydrocarbon emissions into carbon dioxide and water. And they also reduce nitrogen oxides to elemental nitrogen and oxygen. Additionally, three-way catalysts employ onboard computers and oxygen sensors that help optimize systems' reduction efficiencies.

In response to increasingly stringent emissions standards, manufacturers continue to equip new cars with ever more sophisticated emission control systems. The enduring evolution of emissions reduction technology has occurred in three principle arenas: (1) engine design, (2) fuel related technologies, and (3) exhaust gas aftertreatment (DieselNet 2002).

In the arena of diesel emission reduction, DPFs and Diesel oxidation catalysis (DOCs) have gained widespread use in locations where their application is not impeded by excessively high fuel sulfur concentrations. These devices can significantly reduce the amount of diesel particulate matter that is emitted into the environment. Also, selective catalytic reduction (SCR) and lean NO_x-trap (LNT) technologies show the most promise as solutions to achieve the strict NO_x standards.

Intense international attention is now focused on efforts to reduce or eliminate sulfur from gasoline and diesel fuels as well as lubricating oil. The elimination of sulfur from diesel will facilitate the ubiquitous employment of catalytic technologies in gas and diesel applications. Because sulfur in diesel increases SO_x emissions – which are known to oxidize in catalytic devises and combine with moisture to create sulfuric acid – the elimination of sulfur will mitigate environmental consequences associated with sulfuric acid (i.e., acid rain), which causes acidification of waterways, crop damage, etc.

In the United States, vehicle emissions were subjected to further reductions by provisions of the 1990 Amendments to the Clean Air Act. The Amendment's mobile source provisions required: increased durability, improved control of evaporative emissions, and computerized diagnostic systems that identify malfunctioning emission controls (DieselNet 2004).

The EU also has control over regulation of emissions in EU member states (the European Commission's "Euro Standards"). Since the Euro 1 stage, EU regulations introduced different emission limits for diesel and petrol vehicles. Diesels have more stringent CO standards but are allowed higher NO_x emissions. Petrol-powered vehicles are exempted from PM standards through to the Euro 4 stage, but vehicles with direct injection engines will be subject to a limit of 0.005 $\mathrm{g\,km^{-1}}$ for € 5 and 6. A particulate number standard (PN) is part of € 5 and 6, but is not final. The standard is to be defined as soon as possible and at the latest upon entry into force of Euro 6 (EC 2007).

Other countries have developed their own standards, or are participating in 'cross-regional programs,' whereas some such as Brazil have chosen to adopt the standards of other nations.

The above combination of ICE and end tailpipe technology, policy making, and legislation reduced to a large extent road transportation emission of urban pollutants even while fuel use and vehicle kilometers traveled increased. As already mentioned, since the 1980s exhaust emissions of CO, NO_x, hydrocarbon, and PM from new vehicles have been reduced by about a factor of 10–100 (Krasenbrink et al. 2005).

3.13.4.2 GHG Emissions

Almost all industrialized countries use standards on new vehicles to reduce vehicle fuel consumption and CO_2 emissions. Because of various historic, cultural, and political reasons, different countries and regions have chosen to adopt different fuel economy (FE) or emission standards (ES). These standards differ in stringency, by their apparent forms and structures, and by how the vehicle FE or GHG emission levels are measured – that is, by testing methods. They also differ by implementation requirements, such as mandatory versus voluntary approaches.

The research on FE improvement potential clearly suggests that there is scope for progressively tightening standards over a longer time frame, with milestones for a 30% improvement over current levels by 2020 and around 50% improvement by 2030 or soon after. Such standards would be valuable for increasing regulatory certainty for manufacturers faced with long investment cycles, enabling them to bring new technology to market. In addition, research shows that FE mandatory standards enable greater GHG emissions reductions (on average 2–3% per year) than voluntary systems (on average 0–1% reductions per year). Regulation and standard setting is a powerful tool in reducing emissions and cleaning up transport. Regulatory certainty also facilitates the development of advanced technology. However, very few countries outside the OECD have developed fuel economy policies, standards, and regulations.

More than 75% of the world light duty market has FE, fuel consumption, or CO_2 standards. There are a range of approaches to standard setting across countries, and target rates of FE improvement may differ, but all have the same goal of promoting more efficient new cars. Standards for the world's largest markets are summarized in Table 2. GHG emissions of HFCs from air conditioning systems are included in US and EU standards, based on new technologies that provide 'off-cycle' emission reductions.

Countries concerned with energy/oil security have preferred FE or fuel consumption as a metric; in the latter case, fuel consumption ($\mathrm{l\,100\,km^{-1}}$) is preferred over fuel economy ($\mathrm{km\,l^{-1}}$). Countries focusing on climate issues have preferred CO_2 of GHG emissions as a metric (in this case the GHG standard includes air-conditioning N_2O, and CH_4 emissions).

The form of the standard varies. Almost all countries now use a corporate average instead of minimum or maximum value standards because fleet averaging offers a greater incentive to improve across models, whereas there is no incentive to improve vehicles that already comply with a value standard. In addition, fleet averaging allows greater flexibility for automakers to sell a diverse fleet of vehicles. Among fleet average standards, some countries use a single standard that the entire fleet must comply with. Other standards use an attribute of the vehicle to differentiate, with the standard varying according to either weight of the vehicle or footprint (size). Under a weight-based standard, engine downsizing improves efficiency but also reduces vehicle weight, which may also expose it to a stricter standard. The way the standard varies according to weight can be adjusted to put more or less pressure on heavier vehicles to improve fuel economy. Weight-based standards provide fewer strategy options for automakers to use technology and fleet composition shifts to comply with standards. Figure 16 summarizes the actual fuel consumption data in place and nearest targets enacted or proposed thereafter by selected countries around the world – making adjustments for differences in test cycles in different countries. The standards currently in place cover a relatively short period of time; none extending beyond 2020.

A large part of the early success in increasing fleet-average vehicle fuel economy and CO_2 emissions is due to vehicle dieselization. This trend occurred in Europe due to the inherent efficiencies of diesel engines and higher energy content of diesel. However, it has been argued that dieselization of the passenger vehicle fleet did not result in overall decrease in vehicular GHG emissions. It has been argued that there have only been marginal energy and CO_2 emission savings as a result of this large shift to diesel engines, particularly because the vehicles tend to be heavier and they tend to be driven more than gasoline vehicles because of lower diesel prices and better fuel economy (Schipper and Fulton 2008). Further analysis showed that fuel taxes must act in harmony with fuel economy policies in order to ensure the overall increase in efficiency and reduction in fuel consumption (UNDESA 2011).

Approaches in which the entire industry must meet one target contrast with the US CAFE policy, which requires each company to meet standards for cars and light trucks. EU's (and Japan's) approach is based on a more coordinated market economy perception (in which the government aims to develop consensus between powerful business actors, both via laws as well as by way of constructive discourse), versus a sense that fuel economy regulations is an unwelcome market intervention. It seems to work better in improving the fuel efficiency and CO_2 emissions of new vehicles sold – skewed, however, by the human tendency to consume more.

3.13.5 The State of Things and the Future Potential

Before any discussion concerning the future potential of energy – transportation relation, it is useful to keep in mind the characteristics of unsustainable and sustainable transport (Table 3).

Obviously, the current transportation system is unsustainable. So, the question is: 'Should we expect to ever achieve a sustainable transportation system?' Some commentators believe this is an unattainable goal. In the case of 'sustainable development,' Glasby (2002) argues for a totally new paradigm because, in his view, the world is embarked on a course that is manifestly unsustainable. That may be so in the case of sustainable development, but that doesn't mean that we can't develop a transportation system that is more sustainable than the one that currently exists.

Table 2 Fuel economy and GHG standards for vehicles around the world

Country/region	*Metric*	*Structure*	*Test method*[a]	*Programme details*[b]	*Implementation*
European Union	CO_2 emissions ($\mathrm{g\,km^{-1}}$)	Overall light-duty fleet	EU NEDC	40% Reduction MY 2008–20	Voluntary
USA	FE (mpg) and GHG equivalent ($\mathrm{g\,CO_2eq\,mi^{-1}}$)	Cars & light trucks	US FTP 75	20% Reduction MY 2011–16	Mandatory
Japan	FE ($\mathrm{km\,l^{-1}}$)	Weight-based	Japan JC08	19% Reduction MY 2010–15	Mandatory
China	Fuel consumption ($\mathrm{l\,100\,km^{-1}}$)	Weight-based	EU NEDC	12% Reduction MY 2008–15	Mandatory
Canada	GHG equivalent ($\mathrm{g\,CO_2eq\,mi^{-1}}$)	Cars & light trucks	US FTP	20% Reduction MY 2011–16	Voluntary
Australia	Fuel consumption ($\mathrm{l\,100\,km^{-1}}$)	Overall light-duty fleet	EU NEDC	10% Reduction MY 2004–10	Voluntary
Taiwan/South Corea	FE ($\mathrm{km\,l^{-1}}$) and CO_2 emissions ($\mathrm{g\,km^{-1}}$)	Engine size	US FTP	13% Reduction MY 2012–15	Mandatory

Table 3 Key characteristics of unsustainable and sustainable transportation

	Unsustainable transport	*Sustainable transport*
Transportation volume	Requires a high level of numbers of trips and trip distances, because of sprawled urban development and inefficient logistical networks	The demand for travel is minimized and journeys are short, because of compact urban development, mixed land use, and optimized logistical chains
Transportation modes	Reliance on private motorized transport for passengers, and heavy goods vehicles for freight	Most passenger trips are made by public or nonmotorized transport, and freight is carried by rail and other low-carbon modes
Transportation technologies	Vehicles rely on inefficient, fossil-fuel engines	Low carbon vehicle technologies are mainstreamed, including highly efficient engines, hybrids, plug-in hybrids and electric vehicles
	The transport network is inefficiently managed	New technologies such as 'Intelligent Transport Systems' and 'Smart Logistics' help manage transport systems in highly efficient ways.
Transportation pricing	The price paid by users for vehicles, fuel, parking, and road space do not cover the full external costs to society, encouraging motorized vehicle use at the expense of more sustainable choices	The price paid by transport users fully 'internalizes' the true costs, managing growth in motorized vehicle use and encouraging environmentally friendly alternatives
Resilience to climate	Transport systems are highly vulnerable to the climate	Transport assets are screened against vulnerability criteria, and are developed in a way that is resilient toward possible changes in climate

Sci. Interface.*

Focusing on road transportation, any discussion on the future potential has to be based in the complex shown in Figure 17. The importance of each component depends on the application but the general scheme is the same (Schulte and Wirth, Undated; ACEA 2011). Because space is limited for a full discussion of this complex, we only briefly comment on energy and environmental issues in conjunction with some customer expectations.

Regarding customer expectations, trends are very similar for gasoline and diesel engines, especially in the volume segments and markets. Customers are very focused on total cost of ownership, which is determined by such factors as price, resale value, fuel consumption (and fuel price), maintenance cost, as well as reliability, safety, and durability. At the same time, customer expectations regarding 'fun to drive' are still increasing. This translates into a continuation of the 'power and

torque race' to further improve vehicle performance and drivability. In addition to performance improvements, at steadily rising fuel prices, customers are expecting further improvements in fuel economy.

Gasoline engine technology is currently entering a new phase of intense development and technology deployment based on two major drivers: On one hand the further intensified pressure for fuel economy improvement, which has got another acceleration by recent fuel price increases, leaving the customer in an unprecedented uncertainty in terms of energy supply resulting in much more cautious purchase decisions regarding vehicle size and powertrain technology. On the other hand, drivability refinement and torque characteristics are powertrain attributes that are meanwhile positively associated primarily with modern diesel engines and therefore the gasoline engine is endangered to lose its classical footprint as being the more refined engine for the demanding customer. It is meanwhile widely accepted (Wirth and Schulte 2006) that engine downsizing in combination with pressure charging (primarily turbocharging) is the most appropriate technology bundle to address the two key challenges mentioned above at the same time. It also has been discussed in depth that direct injection is a technology with high synergy potential to further enhance the merits of turbocharging.

The available technology options for CO_2 reduction can be divided into three groups (Wirth and Schulte 2006):

- Aggressive friction reduction (including options like on-demand water pump, offset crank, variable oil pump) and thermal management (including options like split cooling and heat storage), as well as high compression ratio enabled by homogeneous direct injection.
- Downsizing, including a change of the engine architecture to the next smaller engine family plus turbocharging.
- Stratified part-load operation with key enabler the spray guided stratified combustion system, with its best possible fuel economy improvement versus homogeneous operation.

Further, meeting even higher levels of pollutant emissions controls will require aftertreatment technological advances. Catalysts with lower thermal mass and light-off temperature that can be coupled to the exhaust manifold will be required. Catalysts are needed to very efficiently adsorb emissions during cold-start operations. Sophisticated models of energy operation, including predicting emissions when going from transient cold-start to full-throttle operation, coupled with a catalyst aftertreatment operating mode that can deliver precise individual-cylinder air/fuel control must be developed.

Today, along with gasoline and Diesel, engines that use more than one fuel are on the market and an increasing future demand is assumed for alternative fuels and particularly CO_2-neutral fuels. The current and short-term fuel mixture includes:

Fossil fuels. Second to oil, natural gas (NG) is the most commonly used fossil fuel in transportation. NG is likely to become the most significant energy product throughout the next 30 years (Bilgin 2009). Diesel can also be generated synthetically via the Fischer–Tropsch process from natural gas.

Biofuels. Bioethanol and biodiesel, the former using fermentable plant material to produce combustible ethyl-alcohol, and the latter using plant and even animal oils to produce combustible fuels via transesterification. The global annual production of biofuels increased 17% in 2010 to reach an all-time high of 105 billion liters up from 90 billion liters in 2009. At the end of first decade, ethanol global production was more than three times that of 2000 and biodiesel production more than ten times (IEA 2012). Currently, biofuels provided 2.7% of all global fuel for road transportation – an increase from 2% in 2009. Current biofuels production technologies use established arable crops and feedstock cost is a major element of the biofuel production economics because prices of these established crop feedstocks are volatile. There is a threshold above which biofuel cannot produced without threatening food supplies and biodiversity. Second-generation biofuels production (produced sustainably by using biomass consisting of the residual nonfood parts of current crops), when stabilized, is expected to surpass these problems.

Electric and hybrid electric vehicles. Electric vehicles offer a number of advantages, such as low noise levels and virtually no toxic emissions during operation. Emissions occur elsewhere, however, during the production of the batteries and the electricity needed to recharge them. Still, extensive use of such vehicles has been inhibited by the current limitations of battery technology, such as limited driving range, and by high costs, restricting their use to special niche applications. A breakthrough for battery-powered vehicles seems unlikely in the near future, even though batteries are constantly becoming cheaper and more efficient. It would be better if the electricity were produced aboard the vehicle, which is one of the reasons why many automakers appear to be focusing instead on hybrid electric vehicles or on fuel cells. Hybrid electric vehicles combine the ICE of a conventional vehicle with the battery and electric motor of an electric vehicle. A further development is the introduction of plug-in hybrids, that is, full hybrids that can be recharged both by the vehicle driving cycle and by external sources. A hybrid is more expensive and heavier than the corresponding conventional vehicle, but might cut fuel consumption and toxic emissions by about half in urban driving. GHG emissions may well be reduced compared with an equivalently sized ICE vehicle, but total emissions will depend on CO_2eq intensity of the electricity drawn from the grid.

Fuel cells. With the use of hydrogen fuel cells, hydrogen is converted via electrochemical means into electrical energy to power a motor. This results in zero emissions at source, thereby ensuring considerable health and environmental benefits, as well as reduced noise. City buses, because of relatively lower barriers, might be among the first fuel cell-equipped vehicles used on a larger scale. Building a general hydrogen infrastructure would take a long time and involve substantial costs. The introduction of fuel cells for vehicles would be facilitated by the use of a liquid fuel instead of hydrogen gas, because the infrastructure for liquids is mostly in place, and some fuel cells already utilize liquid fuels directly.

Using projections based on the this fuel mixture and technological advances on the ideal cases of appropriate timing of air pollutant emission regulation implementation in developing countries and investment in reducing the sulfur content of petroleum products for road transport to or below 10 ppm in all countries, road sector emissions would approach zero in 2050 (Takeshita 2011) (**Figure 7**). In the case of urban pollutants and despite the differences in the fuel mixture scenarios, the potential for further reduction is clearly indicated.

Projections of CO_2 emissions are more uncertain. In effect, results basically depend on the fuel mixture assumptions. Estimations for scenarios ranging from no CO_2 mitigation policies (Business-as-Usual Scenario) to CO_2 mitigation policies combined with optimistic cost assumptions – the specific costs of the components of hybrid vehicles, electric vehicles, and fuel cell vehicles not included in baseline gasoline or diesel ICEs are assumed to reach levels that are 50% lower than their reference specific costs. (**Figure 18**) shows that reduction is possible only in cases of CO_2 mitigation policies with optimistic cost assumptions. The best result demands that the share of hybrids, especially plug-in hybrids, is almost 100% of the global fleet (light-duty vehicles, buses, and medium-duty trucks) in 2050. In this case, global road fuel consumption in 2050 decreases by about 28% compared with the Business-as-Usual scenario, and road transport accounts for 16% of the total global CO_2 emissions reduction in the same year. This requires lowering of the specific cost of batteries for the penetration of plug-in hybrids. This scenario indicates further that the increasing penetration of hybrids leads to the reduction in the number of road vehicles fueled by biomass-derived FT synfuels under the CO_2 emission constraints. These results show that except for electric two-wheelers, pure electric vehicles and fuel cell vehicles are transport technologies that might play a role in the second half of the century and/or in a more carbon-constrained world, a demand which is equivalent to an energy paradigm change.

This is clearly indicated in **Figure 19**, which shows the CO_2 abatement measures potential (well-to-wheel emissions, from 2006 (base year) to 2030) of passenger cars in comparison with a no-action baseline and in **Figure 20**, which shows the potential development paths for the automotive sector. The three abatement paths represent different approaches to improving the carbon efficiency of passenger cars (McKinsey & Company, 2009a): (1) hybrid and electric, (2) mixture of hybrid, electric, and ICEs (mixed technology), and (3) optimized ICEs. The paths differ in the rate and time over which particular technologies penetrate the global vehicle fleet, leading to different penetration levels in 2030. The scenarios assume an aggressive reduction in the carbon intensity of electricity generation and share the same assumptions for

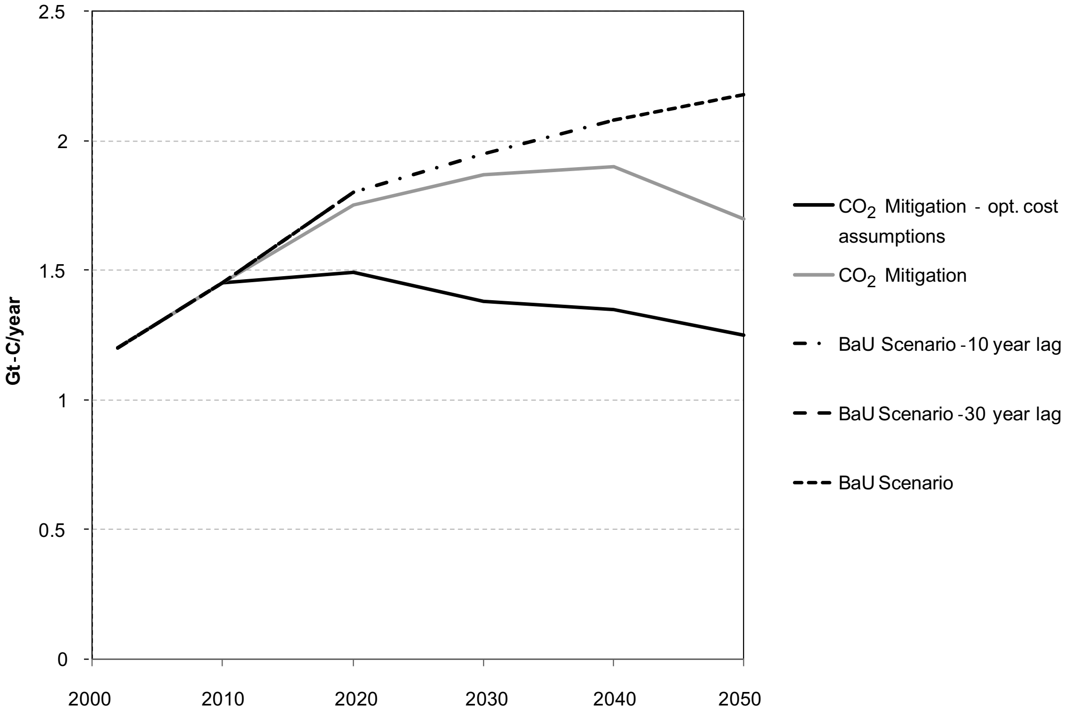

Figure 18 Global emissions of CO_2 from road vehicles for five scenarios: Business-as-Usual (BaU) scenario, the CO_2 mitigation scenario, the BaU scenario with a 10- or 30-year lag (refers to developing regions) and the CO_2 mitigation scenario with optimistic cost assumptions. Source: Takeshita, T., 2011: Global scenarios of air pollutant emissions from road transport through to 2050. *Int. J. Environ. Res. Pub. Health*, **8,** 3032–3062.

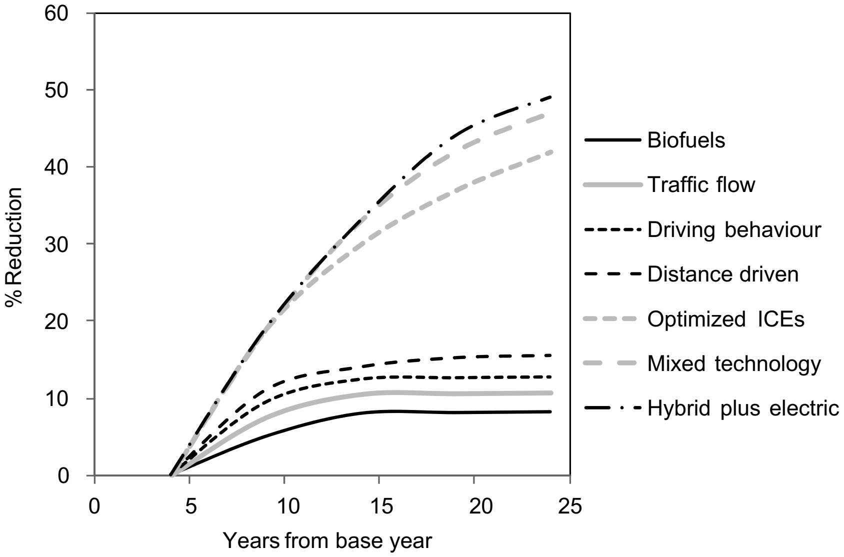

Figure 19 Global passenger vehicle CO_2 emissions abatement potential (base year: 2006). Emissions reductions for biofuels, traffic flow, driving behavior, and distance driven are based on mixed technology scenario. Source: McKinsey & Company, 2009a: Roads toward a low carbon future. Reducing CO_2 emissions from passenger vehicles in the global road transportation system. [Available on line at http://documents.eu-japan.eu/seminars/europe/other/co2_reduction/dinkel_report.pdf.] Assessed at 15 Feb 2012.

abatement using other measures (biofuels, traffic flow, shift to public transportation, ecodriving).

As shown in Figure 19, the hybrid and electric scenario gives a 49% reduction relative to the no-action emissions baseline and a 22% reduction relative to 2006 emissions levels. This represents an aggressive scenario assuming a rapid transition toward electricity-based propulsion systems and infrastructure in place to support them. All remaining ICE systems would be optimized for 130 g $CO_2\,km^{-1}$ in 2030 (well-to-wheel emissions). Mixed-technology scenario gives a 47% reduction

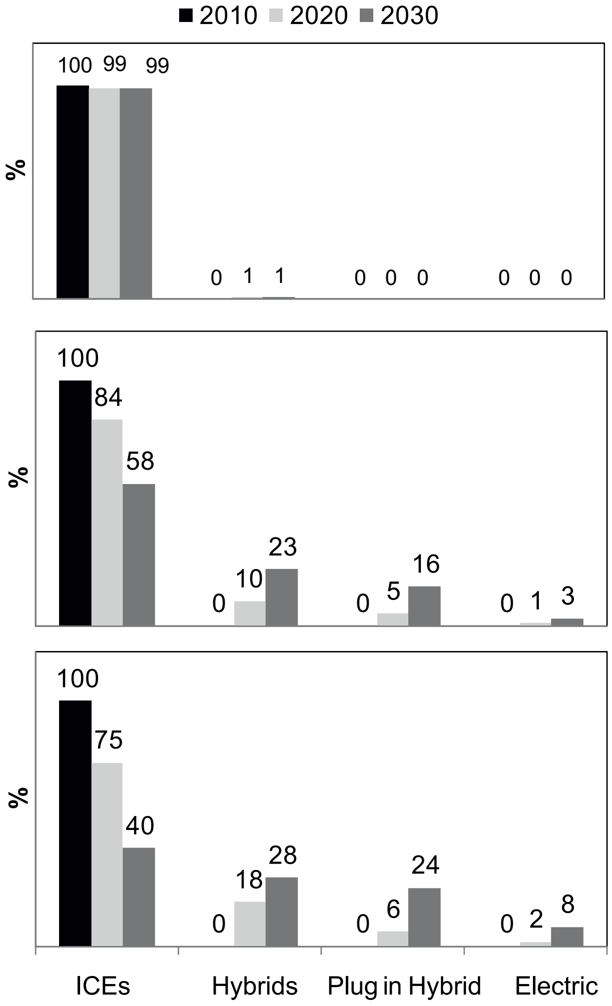

Figure 20 Potential development paths for the automotive sector. Percentages refer to vehicle fleet share. Source: McKinsey & Company, 2009b: Pathway to a low carbon economy. Version 2 of the global greenhouse gas abatement cost curve. [Available on line at http://www.mckinsey.com/Client_Service/Sustainability/Latest_thinking/Pathways_to_a_low_carbon_economy.] Assessed at 15 Feb 2012.

relative to the no-action emissions baseline and an 18% reduction relative to 2006 emissions levels. ICE systems would be optimized for 150 $\mathrm{g\,CO_2\,km^{-1}}$ in 2030 (well-to-wheel emissions). Emissions reductions for biofuels, traffic flow, driving behavior, and distance driven shown in Figure 19 are based on this scenario. ICE scenario gives a 42% reduction relative to the no-action emissions baseline and an 11% reduction relative to 2006 emissions levels. ICE systems would be optimized for 170 $\mathrm{g\,CO_2\,km^{-1}}$ in 2030 (well-to-wheel emissions). Similar results are produced for medium and heavy duty vehicles as well (McKinsey & Company, 2009b).

3.13.6 Conclusions

In identifying the essential components of energy and transportation relationship some specific features were revealed.

First, because of the combination of scarcity in cheap oil, increased global energy demand, and greater supply disruptions provoked by geopolitical dependence of Europe, fuel prices will continue to rise in the medium and long term. Indeed, mostly due to the emerging economies in Asia (in particular China and India), energy demand is rising significantly more than oil production and oil refining capacity, making disruptions in energy supply a major and increasing concern. The share of worldwide energy demand and energy market stress that these markets bring along with their expansion is overwhelming. The growth of mobility and transport systems in most emerging economies has progressed at a different speed – India and China had a slow start but have now surpassed Western regions in their economic growth rates, which is directly reflected in their transport demand, mobility growth, and increased energy demand.

Second, the green message – uses less energy – is not going to solve the problem unless economic growth stops at the same time. If it does not, any efficiency saving will soon be eaten up by higher consumption per head. Technology development policies making vehicles more energy efficient or promoting alternative propulsion systems are successful in reducing fuel consumption per kilometer, but tend to result in longer distances traveled by both passengers and freight.

Third, exponential urban expansion in developing countries is one of the major environmental challenges of this century. Current trends in urban developments are a reason for concern in terms of climate, because they are allowing private cars to gain predominance over public transport or nonmotorized travel. No matter if the mode share of automobiles is low, as in emerging economies, or very high, as in the developed world, the trend is clear: people are buying more cars every day and once they have them, they use them. Consequently, the energy use and greenhouse gas emissions from urban passenger transportation are continuing to increase.

Fourth, as a consequence of the trends just mentioned, and despite the technological progress in automobile toxic emissions, air pollution is and will continue to be a health issue in the megacities of the developing world, mainly due to the existence of old and malfunctioning vehicles.

Fifth, rail is several times more energy efficient than road shipping and aviation, emits significantly less emissions, and has the potential to improve further.

Sixth, oceangoing shipping and resulting emissions produce significant impact on atmospheric composition and climate. Control of NO_x, SO_2, and PM emissions from ships will have beneficial impacts on air quality, acidification and eutrophication, whereas CO_2 reductions will be beneficial in the general effort to reduce these emissions.

Seventh, the growth of air transport is a crucial dimension of the overall environmental impact of aviation. The latter therefore requires interpretation in the context of the rapid growth of aviation and most of its emissions.

Eighth, our ability to monitor and understand the atmosphere has taken a quantum leap in recent years. We have gone beyond naïve linear models and now appreciate that if complex systems such as the atmosphere, the oceans, and land ecosystems change, they may become unstable and more unfriendly.

Ninth and last, the share of world transportation energy use attributed to petroleum-based liquids does not change significantly over the projection period, but oil's dominance may begin to be challenged by advancing technologies. Uncertainty about the security of oil supplies, the prospect of rising oil prices, and environmental concerns about emissions associated with the combustion of petroleum pose challenges to countries that are experiencing rapid motorization and have to import large portions of their transportation fuel supplies. As a result, future trends in transportation demand will be influenced by government policies directed at reducing emissions and congestion while promoting alternative fuels, advanced vehicle technologies, and mass public transportation.

3.14.1 Introduction

Anthropogenic climate change has been an increasingly interesting issue of research during the last decades, primarily aiming at the identification of future-related threats and possible ways of alleviating the related harmful effects. Since anthropogenic climate change was acknowledged by the academic society, policies to combat climate change have partly been included in the decision-making agenda. Following the Stern review (2007), which recognized early action for decreasing greenhouse gas emissions as the most cost-efficient path for a successful climate policy, numerous policies have been introduced that aim at the mitigation of greenhouse gas emissions. One leading example is the launch of the Energy Package for 2020 (http://ec.europa.eu/clima/policies/package/index_en.htm) by the European Commission which identifies the crucial role of the energy sector in taking action against climate variability. Nowadays, climate policy has already been incorporated in energy policy formulation, and the attempt to internalize the external societal costs of emissions has proved crucial for the formation of the future energy mix of the world.

While a low-carbon power generation system and an overall 'greener' energy mix have been set as a priority in decision making, measures to adapt to a changing global environment have not gained much attention. Academic research on the vulnerability of the energy sector to climate variability has been limited so far and thus has not facilitated a thorough understanding of the impacts of climate variability to energy systems. Moreover, the location-specific impacts of climate variability in combination with the different energy mix of each location make the assessment of climate variability effects and of possible adaptation measures extremely case-specific and difficult to generalize. The prevailing uncertainty related to timing and intensity of climatic effects complicates the proper incorporation of adaptation parameters in future energy planning.

Energy infrastructure in most regions of the world is soon to be reinforced, replanned, and rebuilt owing to increasing demand from developing countries and decreasing lifespan or revised environmental regulations in developed countries, thus bringing a period of large investment plants in the energy sector. Climate vulnerability should be appropriately considered at all levels of energy infrastructure planning, especially because of the very long lifetime (40–80 years) of energy systems. An attempt is made in this chapter to specify the impacts of climate variability on large energy projects and propose possible climate-proof solutions for future energy projects.

In this chapter, a brief review on the impacts of climatic variability on different forms of energy supply is given in order for the reader to understand the context in which large energy projects are under climate-related risks. The analysis then focuses on thermal power plants and in particular on nuclear plants and concentrated solar thermal plants, because both technologies are integrated only in a centralized and large-scale manner. An attempt is also made to provide a number of concrete adaptation measures and proposals to policy makers. The scope of this analysis is to raise awareness and provide some insights with regard to the vulnerability to climate change of large, centralized power plants; consequently, energy security can be enhanced along with prioritization of optimum win–win mitigation and adaptation plans.

3.14.2 Vulnerability to Climate Variability

As mentioned, there is still a high level of uncertainty as regards the various aspects of climate variability and the intensity of the related effects, while the future pace of climatic change shows the highest uncertainty levels. This article will be based on robust scientific and empirical climatic evidence that has been observed currently or is expected in the future. In brief, the main observed anthropogenic climate change according to the IPPC (http://www.ipcc.ch/) 2007 report includes the following:

1. An increase of the global average temperature and an increased rate of warming.
2. Snow, ice, and frozen ground are affected by increase melting, instability of permafrost, and reduced tropical glaciers.

http://dx.doi.org/10.1016/B978-0-12-384703-4.00323-3

3. Increased or decreased runoff according to the location.
4. Increased frequency of extreme events.
5. More frequent heat waves, less cold days and nights.
6. More frequent heavy precipitation events possibly leading to floods.
7. More frequent intense cyclone activity.
8. Sea level has risen an average of 18 cm since the nineteenth century.

Projections for expected future climate variability are based on the above-mentioned observations and greatly depend on the time scale under analysis. Projected changes in surface temperature, wind patterns, solar radiation, sea level, permafrost, and rainfall along with extreme weather events are expected to occur depending on time and space. Certain weather variables of the long-term future climate projections deviate less than others; for example, average temperatures are more robust than the expected levels of precipitation.

Anthropogenic climate change as described will affect all aspects of biological, economic, and social life. Assessment of the vulnerability of different sectors, countries, and societies to climate change is necessary in order to prepare against the identified threats. Science is expected to play a vital role in the conceptualization of a sustainable future, both by means of prevention (i.e., mitigation of greenhouse gases and other forms of pollution) and by means of adaptation to the changing conditions. The energy sector is expected to be widely affected by climate variability. At the same time, energy systems are considered central to mitigation policies and thus particular attention must be given to the synergies of mitigation and adaptation measures.

Ebinger and Vergana (2011) in their report for the World Bank publications on the climate impacts on energy systems summarize all major impacts on energy resources and energy supply in **Table 1**. All different sources of energy are affected by climate variability at different levels of intensity. Large energy projects, namely large-scale installations of any form of energy supply, are the dominant feature of current energy systems. Climate vulnerability poses an additional factor of uncertainty which may increase investment costs, if impacts are assessed during the planning of the system, or increase operation costs, if no strategic adaptation measures are taken.

Large energy projects generally constitute a significant factor of climate vulnerability for their respective energy systems. Centralized energy systems, that is, systems that feature large energy projects with central dispatching and no geographical dispersion, are found more susceptible to threats of climate variability because of the limited range of diversification and an inability of efficient adjustment. Additionally, energy systems are usually designed for relatively stable weather conditions and planners rarely take into account probable weather extremes. However, central planning and large-scale installations enable proper risk management and economies of scale with regard to the cost of adaptation measures. The parameters affecting the vulnerability of different types of large energy projects should be appropriately assessed. This assessment will facilitate the achievement of long-term energy security goals that are a prerequisite for economic activities and social welfare.

3.14.2.1 Vulnerability of Energy Sector

Recent research on the vulnerability of the energy sector to climate variability categorizes the impacts in two broad categories, namely impacts on resource endowments and impacts on energy supply. Impacts on factor endowments refer to increased fluctuations of energy inputs and unusual disturbances on supply of primary energy sources. Impacts on energy supply refer to vulnerabilities and inefficiencies of the transformation sector and in particular on the technologies that convert primary energy sources to energy services. Large energy projects are a central part of today's energy systems and are found to be particularly vulnerable as compared with smaller and decentralized projects.

3.14.2.2 Vulnerability of Large Energy Projects

3.14.2.2.1 Thermal Power Plants

Extreme weather conditions have been detrimental to the operation of thermal power plants in the past. For example, in the heat waves of 2003, 2006, and 2009 in Europe some nuclear plants had to cut output, triggering fears of blackouts. In 2003, the heat wave in France caused the cut of 4000 MW because of a forced reduction in capacity and/or the turning off of 17 nuclear reactors (IHT 2007). In 2006, the European heat wave caused disruption to the power systems of France, Spain, and Germany because nuclear plants had to cut output or were given special exemption licenses to discharge water above the permitted temperature into the rivers. In 2009, France again had to cut power and import electricity from the United Kingdom similar to 2003 (UCTE 2004). The economic implications of the described failure to adapt to the changing environment were significant, because power utilities had to purchase electricity from the power market in order to meet their contract obligations at prices even 10 times higher than the average seasonal price.

In the following paragraphs, a description of the factors of vulnerability of thermal plants is given.

Water Requirements for Cooling Purposes

Thermoelectric generation requires large amounts of water for its operation. Water is required mainly for cooling purposes but also for water loss in boiler operation, flue gas desulfurization, and ash handling systems. According to statistics (Eureau 2009), it is estimated that 43% of water demand in Europe comes from cooling requirements in power plants. For specific European countries, the share of water demand for cooling in electricity production is even higher, for example in Hungary and Poland where the respective shares are 91 and 71%. As a result of the significant water dependence, considerations are already being made during the planning procedure of new power plants, for example the rejected permission of a new power plant in Arizona because of concerns about water withdrawal from the local aquifer, as noted in the USCCSP report (USCCSP 2008).

In the USCCSP 2007 report, it is estimated that around 94.6 l of water are required for the production of each kilowatt hour by a steam cycle process. Feeley et al. (2008) provide a thorough description of freshwater withdrawal and consumption factors for different power technologies, indicating

Table 1

	Relevant climate impacts			
Item	*General*	*Specific*	*Additional*	*Impacts on the energy sector*
Climate change impacts on resource endowment				
Hydropower	Runoff	Quantity (+/−) Seasonal flows high and low flows Extreme events	Erosion Siltation	Reduced firm energy Increased variability Increased uncertainty
Wind power	Wind field characteristics, changes in wind resource	Changes in density, wind speed Increased wind variability	Changes in vegetation (might change roughness and available wind)	Increased uncertainty
Biofuels	Crop response to climate change	Crop yield Agro-ecological zones shift	Pests Water demand Drought, frost, fires, storms	Increased uncertainty Increased frequency of extreme events
Solar power	Atmospheric transmissivity	Water content Cloudiness Cloud characteristics		Positive or negative impacts
Wave and tidal energy	Ocean climate	Wind field characteristics No effect on tides	Strong nonlinearity between wind speed and wave power	Increased uncertainty Increased frequency of extreme events
Climate change impacts on energy supply				
Hydropower	Water availability and seasonality	Water resource variability Increased uncertainty of expected energy output	Impact on the grid Wasting excessive generation Extreme events	Increased uncertainty Revision of system reliability Revision of transmission needs
Wind power	Alteration in wind speed frequency distribution	Increased uncertainty of energy output	Short life span reduces risk associated with climate change Extreme events	Increased uncertainty on energy output
Biofuels	Reduced transformation efficiency	High temperatures reduced thermal generation efficiency	Extreme events	Reduced energy generated Increased uncertainty
Solar power	Reduced solar cell efficiency	Solar cell efficiency reduced by higher temperatures	Extreme events	Reduced energy generated Increased uncertainty
Thermal power plants	Generation cycle efficiency Cooling water availability	Reduced efficiency Increased water needs, for example during heat waves	Extreme events	Reduced energy generated Increased uncertainty

the significance of the choice of power technology type and also the diversification of plants as regards the actual consumption of water in relation to withdrawal. According to Feeley et al. (2008), values of withdrawal for US power plants range from 0.004 gal kWh^{-1} for air-cooled natural gas combined-cycle plants to 27.113 gal kWh^{-1} for coal plants with once-through cooling systems. As regards actual water consumption, factor values range from 0.002 gal kWh^{-1} for natural gas combined-cycle plants with once-through cooling system to 0.804 gal kWh^{-1} for coal plants with a cooling pond.

Nuclear plants require substantially more water to cool or condense the coolant that is used to cool the reactor core by transferring heat from the core to the turbines. For example, a nuclear plant may require 2 billion cubic meters of water each year for cooling purposes. As a result, many scientists emphasize the contradiction between the positive role of nuclear energy in climate change mitigation efforts and the significant impacts of climate change to the operation of nuclear plants. By building new nuclear power plants to avoid an increase of greenhouse gas emissions, the energy system could become more vulnerable to increased ambient and water temperatures or even to extreme weather events like floods (e.g., the Fukushima accident in Japan was exacerbated by the floods in the installations caused by the tsunami). Because a certain level of anthropogenic climatic changes cannot be avoided, decision makers and future investors should consider this aspect of nuclear energy.

The type of cooling technology of the power plant is an important factor for its water requirements and hence its vulnerability to climate changes. Three main types of cooling technologies can be found in most power plants, namely once-through cooling technology, once-through cooling with cooling tower, and closed circuit cooling. These can be seen in the figure by Koch and Vögele (2009). Once-through systems result in higher temperatures of the water body into which used water is being discharged because the water for cooling is discharged directly to the same water body after leaving the condenser. Excess temperature of the water body can be avoided by installing a cooling tower. The cooling tower uses an air stream in order to cool down the water before discharge, while a large share of the waste heat produced during the thermal cycle of the power plant is discharged through evaporation, thus leaving a lower quantity of water back to the water body. Closed circuit systems recirculate the cooled water back to the condenser, thus decreasing water withdrawal and affecting the temperature of the water body in a minimum way. As Koch and Vögele (2009) state, however, closed circuit systems relate to lower plant efficiencies.

Koch and Vögele (2009) conclude that power plants with closed circuit cooling systems are less vulnerable to fluctuations of temperature. In particular, they find that in a closed circuit system the increase in water demand is only 2% whereas plants with a once-through cooling system present an increase in water demand of 30%. In case water temperature is taken into consideration, power plants with closed circuit systems show a similar increase (Figure 1).

As mentioned in the case of nuclear power technology, planning of a low-carbon power system should incorporate factors of vulnerability to irreversible future climate change. Carbon capture and storage (CCS) technology features similar problems because it can double the demand for water of a thermal power plant, mainly for two reasons. First, the operation of a CCS system requires large amounts of electricity thus increasing the water demand of the actual installation if this additional power is supplied by conventional thermal sources. Second, an additional cooling load is created caused by the heat generated by the amine CO_2 absorption and the compressing of CO_2. According to NETL (2009) and Moore (2010), by 2030 CCS technology can increase water consumption of the US power sector by 80%. Chandel et al. (2011) give lower estimations of the increase in water consumption caused by the integration of CCS technology. In their paper, they analyze the impacts of climate policy-driven future power systems on freshwater use. In their analysis, the power mix alters according to the value of the carbon price, and all new thermal power plants are assumed to use recirculating cooling systems. They find that in a carbon-constrained power system with increased renewable and nuclear penetration, freshwater withdrawals are 2–14% lower than in business-as-usual (BAU) scenario. Actual consumption of freshwater is found near BAU levels in all cases except when the carbon price exceeds US\$50 ton^{-1} CO_2 and retrofitting of CCS is found cost-efficient. In Chandel et al. (2011), however, CCS technology contributes to a 15% increase in water consumption of the US power system. On the contrary, photovoltaic and wind technology contribute to a 20% reduction of water demand if renewables are substituted for coal plants.

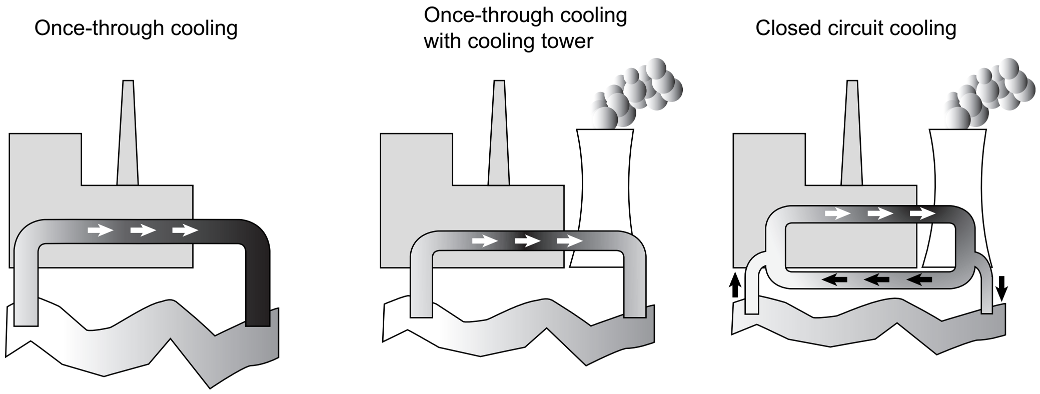

Figure 1

On a European level, Rubbelke and Vogele (2010) examine different scenarios to assess the impact of climatic changes to electricity exchange. They find that in a scenario with increased water scarcity, France will be obliged to reduce its electricity exports because of the large share of nuclear in the country's power mix, which makes it vulnerable to climate variability. Spain and Switzerland will also have to limit nuclear production and subsequent exports. The power system in Germany, although prone to cooling problems, is found easier to adapt. Other countries, like Italy, are affected by reduced cheap imports from France, and so on and thus have to increase domestic supply or find alternative exporters.

Adaptation measures include the consideration of efficient cooling systems and even the installation of water reuse systems, with appropriate treatment in order to protect equipment from increased saline levels. Moreover, once old power plants are to be decommissioned, they are expected to be replaced by more efficient ones that will require lesser amounts of water (and primary energy resources) for the production of 1 kW. Recirculating cooling systems or dry and hybrid air cooling are favorable in terms of water consumption. The latter, however, should not be installed in power plants located in regions expected to face high temperatures, as Chandel et al. (2011) note. An increase in ambient temperatures can also increase water temperatures and affect the plant's cooling efficiency even in wet cooling systems by increasing the demand for water.

Integrated gasification combined-cycle and oxyfuel plants are considered more efficient technologies in terms of water withdrawal and consumption, especially if CCS technology is to be used in order to minimize greenhouse gas emissions. The impact of CCS retrofit on water demand is reduced if amine systems are replaced with postcombustion capture technologies. Overall, research efforts are being made to develop technologies that are less water intensive. Feeley et al. (2008) emphasize the importance of R&D programs that aim at developing technologies that will enable improved water resource management practices in the power sector.

Planning of maintenance shutdowns should take into consideration temperature and water supply parameters; maintenance could be scheduled during months of increased temperatures like July or August in order to avoid unexpected capacity cuts (Rubbelke and Vogele 2010). Moreover, the optimum location of new plants must consider expected long-term impacts of climate variability to the neighboring water body, such as river runoffs, and avoid water-stressed areas.

Power companies that face difficulties related to water supply or legislation on permissible temperature of water discharges have respected their contractual agreements with their customers by purchasing electricity from other utilities. This highlights the importance of power mix diversification, especially in areas that are expected to be affected severely by climate variability. Different forms of power production are affected in a different manner by climate change and thus security of supply can be achieved only by a combination of production technologies. A region highly dependent on nuclear production or thermal power plants with CCS must consider a diversification of future power plant investments in order to avoid extended outages.

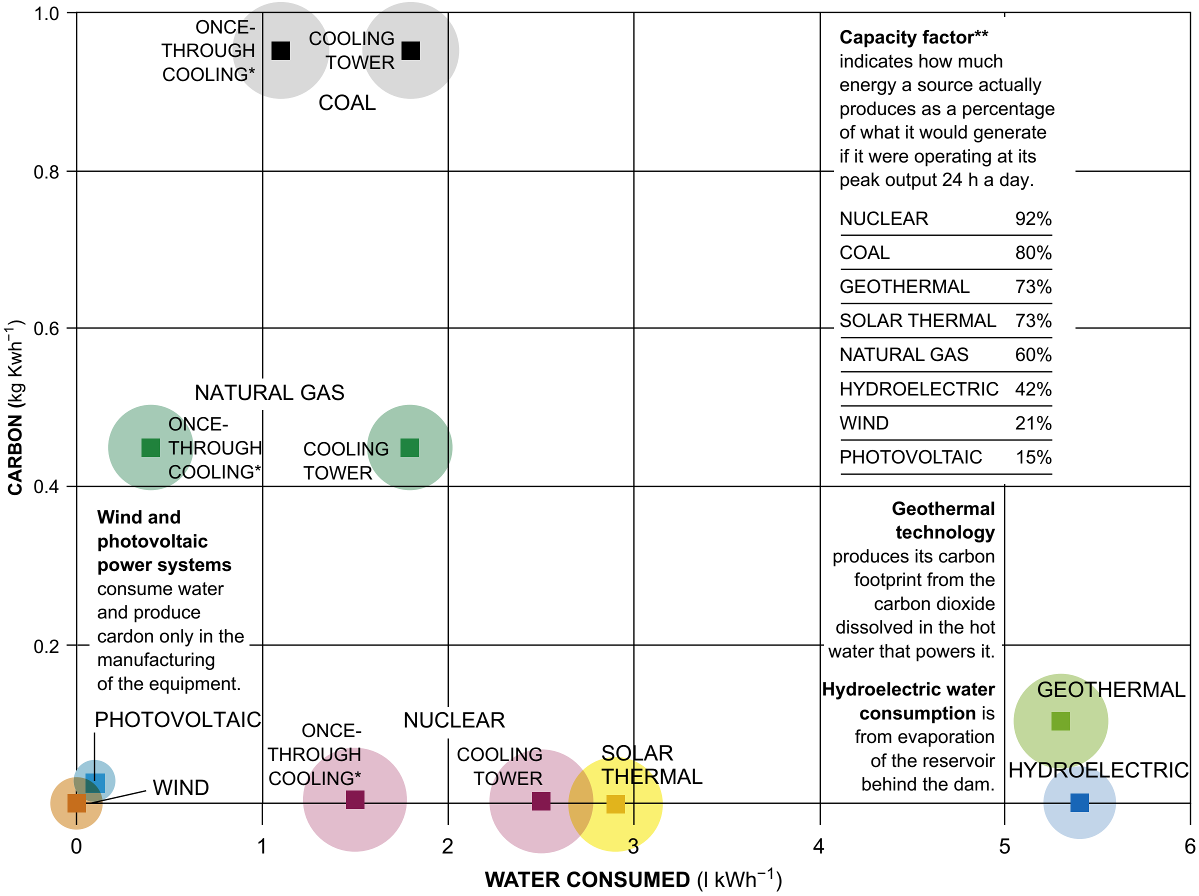
For more information on the water dependence of power plants, see the special IEEE report http://spectrum.ieee.org/static/special-report-water-vs-energy. **Figure 2** comes from the analysis undertaken by IEEE in its report and shows the water and carbon intensity of power technologies.

Impacts of Sea Level Rise and Intense Foods on Plant Operation and Security

Nuclear reactors and other thermal plants are often located along the coasts because of their requirements for water aimed for cooling. A world map of the sites of nuclear plants, which has been created from the extensive database of the International Atomic Energy Agency (http://gcmd.nasa.gov/records/GCMD_GNV181.html), shows that a considerable number of nuclear plants are located along coastlines. Nuclear power plants are given special consideration, owing to the dangerous consequences of possible damage to their equipment and installations. However, regular thermal power plants are also often located on coasts and may face similar difficulties to the ones described below.

A look at past events can distinctly reveal the vulnerability of nuclear plants relating to their location. The catastrophic accident in Fukushima nuclear plant in Japan occurred mainly because of the tsunami wave that ensued after the earthquake, whereas floods (e.g., Missouri River in 2011), storms, and hurricanes (e.g., Katrina in 2005) have posed significant risks to nuclear plant operation on several occasions. Problems related to the events mentioned may include fatal malfunctions of the reactors, the fire-safety systems, or the security and/or communication systems, thus putting in danger the safe operation of the power plants. During past events it has been seen that it is crucial to maintain access to external provision of electric power in order to be able to cool the reactor's cores. Moreover, extreme weather events may cause more floods and thus put in danger the plant's operation by flooding installations, damaging equipment, and stopping communication between the plant and external operational systems. This was the case in the 1999 flooding event in Le Blayais nuclear plant in France and more moderately in 2003 again in France, where according to Kopytko and Perkins (2011), mud and debris in the water used for cooling purposes caused damage to the cooling system and led to the shutting down of nuclear plants in the affected area.

Climatic change is expected to result in a rise of sea level, thus causing concerns for all infrastructure located on the coastlines. Although power plants are usually located a few meters or tens of meters above the sea and the mean sea level rise is not expected to reach that magnitude, sea level rise may in some cases interfere with the functionality of coastal installations (e.g., Committee on National Security Implications of Climate Change for US Naval Forces) through waves and risen sea level that is created from storms and hurricanes. The latter are actually expected to have a more severe impact on coastal installations through flooding and wind damage whereas mean sea level rise is expected to create coast erosion and inundation at reactor sites. Other impacts to nuclear production caused by climatic variability may include increased salt sprays that have a long-term effect of corrosion on the plant's equipment. Measures to reduce the vulnerability of thermal plants to sea level rise and extreme weather events



**Once-through cooling* dumps heat into surface water and returns the water to its source. Relatively little water is actually consumed by evaporation, but much more water must be available for the power plant to withdraw.

**Circle size indicates capacity factor.

Figure 2

include careful siting for new investments and advanced weather monitoring systems for all new and existing plants that can enhance timeous reactions.

As Kopytko and Perkins (2011) conclude in their research findings on the vulnerability of US coastal nuclear plants, most plants are found to have a high coastal vulnerability index mainly because of tides, storms, and increased sea level and less owing to erosion and waves. However, they conclude that coastal plants may face less severe consequences from climatic variability than inland plants especially if power demand is taken into consideration, because inland plants may have to force shutdown in periods of peak demand. On the other hand, costs related to adaptation measures or mere restructuring of damages is considerably high. Consequently, they pose the important questions on whether nuclear energy can be a safe and economically efficient mitigation tool, especially because climate variability is limiting the sites suitable for building nuclear plants.

Air Temperature Impacts on Plant Efficiency

In addition to increased water demand for cooling purposes, increasing ambient air temperature can affect the plant's thermal efficiency in a direct manner. The impacts from increased ambient temperature are closely related to each other because the heat differential between the engine and the external environment is reduced; hence, the plant's efficiency is reduced. In particular, ambient temperature affects the efficiency of the Brayton cycle, which in turn affects power output and fuel consumption by increasing the temperature of the air-specific volume of the compressor.

Davcock et al. (2004) have examined the impacts of ambient temperature on gas turbine performance. Their results indicate that a 33 °C increase in ambient temperature would decrease power output and heat rate of an open cycle gas turbine by 24 and 8.4%, respectively. Similar results are found by Kopac and Hilaci (2007) whereby under a 30 °C increase the overall efficiency of the plant is reduced by 4%. The analysis also indicates that ambient temperature has significant impacts on the exergy efficiency and irreversibility rate of the plant's boiler but lower effects on the outer components of the plant. Nevertheless, temperature increases caused by climate change are not expected to reach 30 °C as examined by the studies mentioned; hence, impacts on thermal efficiency are expected to be low.

Schaeffer et al. (2008) have examined the energy supply impacts of two main IPCC climate scenarios for Brazil. They find only 2% power output reduction for gas plants, thus conclude that impacts of increased temperature in Brazil's electricity supply are of an insignificant magnitude. Lineraud et al. (2009) find that a 1 °C temperature increase would affect thermal cooling and thus plant's power output by 0.8% for nuclear and 0.6% for gas plants. Though the results of the research work described previously shows low percentage levels of efficiency loss caused by an increase in ambient temperature, the impact in absolute terms of power output is significant and would require either new investments or would undermine the systems' security of supply.

3.14.2.2.2 Solar Power Plants

Renewable energy plants and in particular large power installations are susceptible to the impacts of climate change, similarly to thermal power plants discussed. Apart from resource vulnerability, which is directly related to climatic conditions owing to the intermittent nature of renewable sources, the installations can be vulnerable to external conditions.

Concentrated solar thermal power (CSP) plants are a promising type of renewable energy. CSP plants collect and concentrate direct sunlight through mirrors (either flat or parabolic) and then focus sunlight to an absorber tube. The central receivers at the top of the absorber tower contain a heat transfer fluid that is heated by direct sunlight and then used to produce superheated steam for the steam turbine generator and produce electricity. A key feature of this technology is the ability of thermal storage which enables operation even in the absence of direct sunlight. On the other hand, CSP technology requires direct sunlight and thus is more susceptible to solar irradiation conditions than PV plants. Because of the requirement of direct sunlight, arid areas are ideal for CSP installations, where solar irradiation is high, direct normal isolation is high, and weather is typically cloudless.

CSP production is based on thermal power generation and thus is characterized by similar aspects of climate vulnerability especially regarding ambient temperature increase. CSP installations are mainly located in arid areas and thus are well prepared for high temperatures. However, climate variability is expected to have distinctive impacts in desert environments; therefore, CSP development must take these into consideration. In addition, because of the intermittency of the energy input and the remoteness of the installations, CSP plant vulnerability to climate change should be assessed before large-scale development of this technology. Huge CSP plants are mentioned widely in the recent energy policy agenda. For example the Desertec project in North Africa is expected to supply clean and cost-efficient electricity to North Africa and Europe by 2050. In order to ensure higher levels of energy security for CSP energy systems, climate change vulnerability must be taken into consideration during planning procedures and the appropriate adaptation measures should be taken (Figure 3).

Reduced Visibility Effects

Sand storms are frequently found in deserts, for example, the Sahara, and are expected to be more frequent in the future because of climate variability; consequently sharp decreases of visibility in areas where CSP plants are installed may affect the plant's generation. Because CSP generation is based on direct sunlight, sand storms may cause the plant's shutdown or reduced operation according to storage options. Problems in

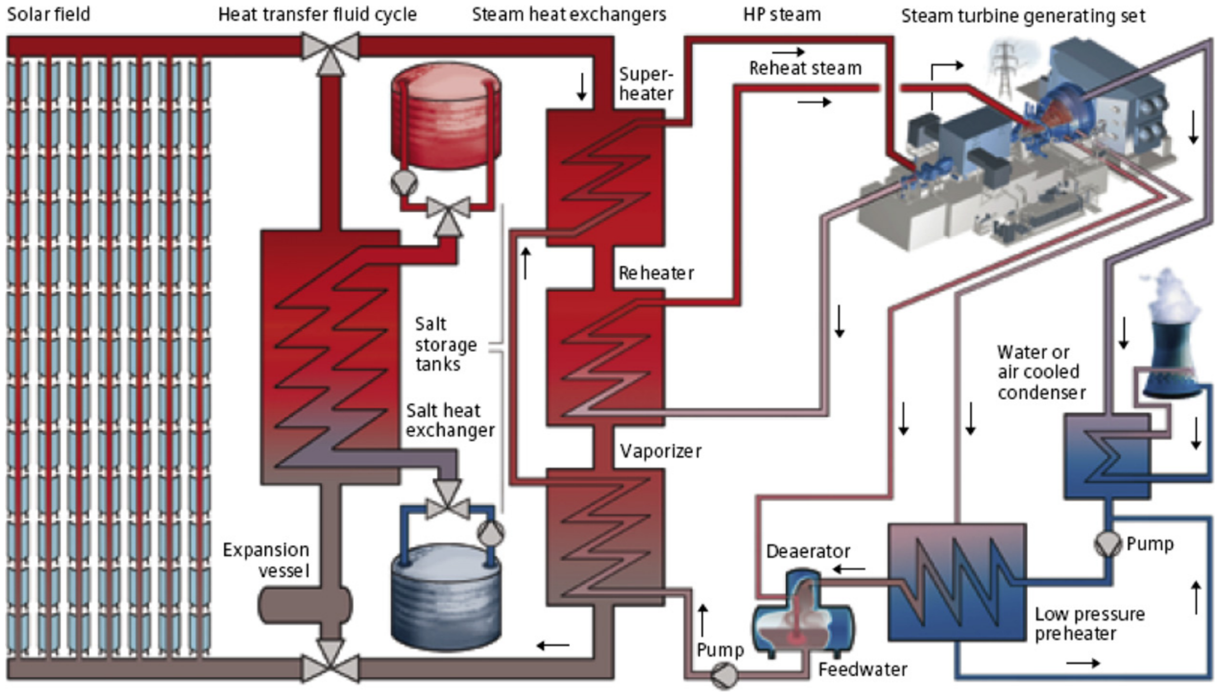


Figure 3

operation or damages of CSP plants during sand storms can be reduced with proper action of the on-site personnel. Examples of good practices include turning the mirrors upside down or covering them in order to avoid damages from sand blasting and proper cleaning of the mirrors after sand storms. On-site personnel are expected to be familiar with similar actions for optimal maintenance and operation of CSP plants on a daily basis, because mirrors will require cleaning in particular hours of the day owing to regular desert winds.

Another reason for reduced visibility and hence for reduced plant power output is increased and prolonged cloudiness. In particular, CSP plants rely on direct solar radiation and thus their operation ceases with diffused sunlight. For this reason, CSP plants are mainly developed in dry areas with short cloud coverage, but climate change may affect cloudiness owing to increased water precipitation, etc. Thermal storage capacity may reduce vulnerability to climatic conditions and substantially increase the plant's efficiency but with a subsequent increase of capital costs. Proper geographical dispersion would also reduce vulnerability of energy systems with high shares of CSP generation.

Temperature Increase Effects

CSP plants are based on thermal generation of a steam turbine which is, as described above, vulnerable to increases of ambient air and water temperature. With regard to water cooling demand, the impacts on CSP plants are expected to be minimal because most CSP plants rely on dry cooling owing to their arid siting. However, ambient temperature determines the efficiency of dry cooling, and according to Patt et al. (2010) a temperature increase from 30 to 50 °C will result in a 3–9% efficiency decrease. Because water cooling is not widely used in CSP plants, no plant outages are expected to be forced by plant operators owing to legislation that protects water temperature of rivers/lakes as in the case of nuclear and other thermal plants.

Research and development for new advanced technologies for parabolic or flat collectors, thermal storage, and dry cooling will determine CSP overall efficiency and vulnerability to climate change. Related considerations must be made prior to finalization of large investment plants that will determine the future energy systems of entire regions.

3.14.3 Conclusions

Energy systems have a key role in mitigating climate change but are also susceptible to climate changes. These two aspects should be central to determining energy policy and the energy systems of the future, along with cost-efficiency considerations and security of supply. Although the role of the energy sector in climate variability mitigation efforts is well understood and widely discussed, adaptation issues are not yet a high-priority policy agenda. It is important to build adaptive capacity that will ensure a secure energy system in spite of unavoidable climatic changes, thus research and development of new energy technologies must also focus on creating adaptive and resilient technologies. It is important to develop a basic knowledge capacity with regard to climate variability impacts on energy systems to avoid extremely vulnerable locations or types of technology.

Awareness, as regards the specific impacts to each energy source, may result in the development of different adaptation responses. Awareness rising from all the different stakeholders is important in order to achieve synergies and incorporate climate risk assessment in all levels of decision making and operation. Scientists, consumers, plant personnel, policy makers, and investors should all cooperate and acknowledge the criticality of adaptation. Scientists relate to new and improved technologies in power generation, more resilient to key climatic impacts. Consumers relate to demand responses and the development of small-scale distributed generation. Plant personnel are responsible for emergency planning and appropriate maintenance of the plant (i.e., cleaning, on-site drainage, and runoff). Finally, policy makers and investors relate to technology and location choice, both critical parameters for energy system vulnerability.

Technological responses relate to specialized research and development programs that will form the required knowledge capacity to achieve protection, better design, and new resilient, efficient, or even 'climate-proof' technologies. Some technological options in this direction are already available whereas others are in the development or demonstration stage. Technological measures include targeted retrofitting, for example, of dry cooling systems for thermal power plants instead of water cooling, or reinforcing of existing infrastructure and developing protective infrastructure such as increasing dam heights and enlarging floodgates.

Adaptation actions include strategic assessment of investments, for example in terms of location choice, as well as changes in operation and maintenance of plants in order to incorporate best practices (e.g., regular cleaning of CSP mirrors) or even include improved meteorological forecasting tools. Moreover, the impacts of climate variability may be reduced by introducing different generation technologies in the energy system, in particular technologies with different facets of climate vulnerability, and/or by introducing geographical dispersion. Diversification of the energy mix is important for hedging climate-related risks and creating resilient energy systems. Decentralized generation will also enhance climate resilience of energy systems, owing to geographical dispersion and reduced probability of large-scale outages.

3.15.1 Transmission Grid Overview

In this chapter, we present a brief overview of the transmission grid in the context of competitive energy markets. The transmission grid plays an essential role by providing the critical interconnection between suppliers and customers. It has been widely recognized that open access via the transmission grid is the key to a competitive electricity industry. However, the basic characteristics and limitations of the network must be properly addressed to achieve open transmission access. If transmission capacity for suppliers to reach customers is sufficient then the energy markets are simple and the market clearing straightforward. However, in most cases, transmission is a scarce resource and the transmission capacity limited. Hence, under normal conditions we need to deal with transmission congestion. The solution to the transmission congestion problem is fundamental to the way energy markets are designed and structured.

Congestion occurs when there is insufficient transmission capacity to simultaneously implement all energy transactions that market participants submit to a regional transmission organization (RTO) in the forward markets, or all actual energy flows that take place in real time. The major impact of transmission congestion is an overall increase in the cost of energy delivery. This cost is manifested by differences in the energy prices among injection and ejection locations in the network.

The simple example of **Figure 1** illustrates the impact of congestion in a system where a supply node A is connected to a demand node B through a transmission interface with maximum transfer capability q_{AB}. Absent congestion, the

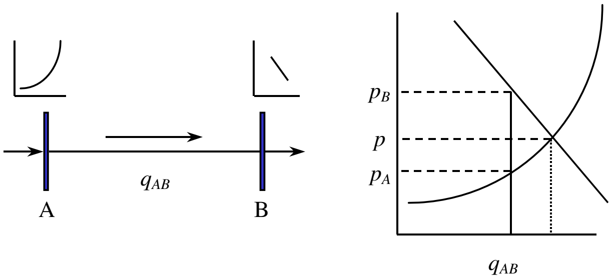

Figure 1 The impact of congestion.

http://dx.doi.org/10.1016/B978-0-12-384703-4.00327-0

market would clear at the intersection of the supply and demand curves at price p. Because of congestion, only q_{AB} can be generated at A and consumed at B. This results in a lower price p_A at A and a higher price p_B at B. The price differential $p_B - p_A$ is the cost of congestion and corresponds to the congestion revenue that would be the outcome of a marginal cost settlement for energy: The demand at B would be charged p_B and the supplier at A would be paid p_A, resulting in congestion revenue. The congestion revenue is usually paid to the transmission owner, either directly or indirectly through transmission rights. In the latter case, the congestion revenue is paid to the transmission rights holders who acquire the rights from the transmission owner through an auction administered by the system operator, (RTO in the United States or transmission system operator (TSO) in Europe).

Financial transmission rights can be used as a hedge against congestion revenues (Treinen and Papalexopoulos 2002, 2005). In the example of **Figure 1**, if the supplier has a transmission right of q_{AB} on the interface A–B, in the direction from A to B, the supplier would be unaffected by congestion because the additional congestion revenue at the price difference of $p_B - p_A$ would elevate its effective price to that of the demand (p_B).

The simplest form of congestion management is deferring it to real time and clearing the forward energy markets as if there were no transmission constraints. This is equivalent to an unconstrained energy pool with a uniform forward energy price for the entire system. This is typical in many European market systems whereby the clearing by a power exchange produces a single price for an entire country. Congestion is addressed in real time by the TSO by an economic dispatch methodology that calculates optimal schedule adjustments to remove transmission constraint violations. To maintain a uniform price, these adjustments can be settled as bid and the net cost recovered by uplift. Clearly, the success of this approach would depend on the severity of congestion and the level of the uplift. If congestion is not small, forward energy market transactions could turn meaningless and large uplifts could distort price signals, creating perverse incentives in the marketplace. Even more significant is the so-called 'dec' game in which suppliers that cause congestion could end up being paid not to generate. This game was prevalent during the energy crisis in California in 2000 and 2001 (Joskow and Kahn 2001).

In a system where congestion cannot be ignored, some level of congestion management is necessary in the forward markets. The focus is to capture the effects of commercially significant and predictable congestion. This approach is compatible with the flow-gate model wherein congestion is observed only on flow-gates in the forward markets. Similarly, a zonal variation would observe congestion only on interzonal interfaces. Any remaining congestion would be insignificant or unpredictable (in which case hedging instruments are useless) and it would not be possible to effectively address it ahead of real time because of insufficient information. This congestion is effectively addressed in real time. It can be priced on the margin, using Locational Marginal Price (LMP) settlement, or settled as bid recovering the net cost by uplift. In this case, however, the uplift ought to be small because significant congestion is already mitigated in the forward markets.

If a detailed transmission network representation is required, congestion is observed in every path of the network. In this case even when one transmission constraint becomes binding, every location in the grid will clear at a different price, resulting in LMPs at every node in the transmission grid.

3.15.2 Transmission Grid Modeling

System operators deploy various methodologies and modeling techniques to study the steady-state operation of the transmission grid under postulated conditions. Various forms of optimal power flow (OPF) techniques and optimization technologies provide this capability. In particular, in the context of energy markets, the purpose of the OPF is to determine the impact of a generation and load pattern on the flows on the transmission grid. These flows can then be checked against operational limits to determine if there are any violations. Power flow (PF) analysis is also deployed to examine the impact of contingencies. This processing is referred to as security analysis.

The steady-state solution of the transmission network requires the solution of a set of nonlinear equations describing the balance of power at each location (bus). This is referred to as the dispatcher power flow (DPF) problem. The AC power flow equations, which describe the power balance at a bus, are a set of N complex equations, one for each bus, of the form

$$-P_{NET_k} + jQ_{NET_k} + V_k e^{-j\theta_k} \sum_{m=1}^{N} (G_{km} + jB_{km}) V_m e^{j\theta_m} = 0 \qquad k = 1, \ldots, N \qquad [1]$$

where

N = the number of electrical buses
V_m = the voltage magnitude at bus m
V_k = the voltage magnitude at bus k
θ_m = the voltage angle at bus m
θ_k = the voltage angle at bus k
$G_{km} + jB_{km}$ = the (k, m)th element of the bus admittance matrix
P_{NET_k}, Q_{NET_k} = the net real and reactive power injections at bus k.

The preceding set of complex equations can be separated into their real and imaginary parts forming two sets of (noncomplex) equations, which can be solved for an unknown set of V and θ.

$$\begin{aligned} &\sum_m P_{km}(V,\theta) - P_{NET_k} = 0 \quad k = 1, \ldots, N \\ &\sum_m Q_{km}(V,\theta) - Q_{NET_k} = 0 \end{aligned} \qquad [2]$$

where

$P_{km}(V,\theta)$ = the million watt (MW) flow on a branch connected between bus k and bus m
$Q_{km}(V,\theta)$ = the MVAR (unit that measures reactive power (1 MVAR = 1,000,000 VAR)) flow on a branch connected between bus k and bus m and the summation is performed over all branches connected to bus k.

The MW flow on the branch k–m can be written as

$$\begin{aligned} P_{km}(V,\theta) = {} & G_{kk}V_k^2 + V_k V_m (G_{km}\cos(\theta_k - \theta_m) \\ & + B_{km}\sin(\theta_k - \theta_m)) \end{aligned}$$

and the MVAR flow on the same branch can be written as

$$\begin{aligned} Q_{km}(V,\theta) &= -B_{kk}V_k^2 + V_kV_m(G_{km}\sin(\theta_k - \theta_m) \\ &\quad - B_{km}\cos(\theta_k - \theta_m)) \end{aligned}$$

The set of equations given by eqn [2] form what is commonly referred to as the Static Load Flow Equations (SLFE). These equations, along with several power flow local control features, form what is referred to as the dispatcher's power flow problem. The local control features are for maintaining a bus voltage at a specified value by varying a generator MVAR output, a transformer tap position, or a voltage control capacitor step position and for maintaining net interchange at a scheduled value. MVAR limits are respected on a generator during this process.

Sometimes, it is convenient to have a more compact notation for the above equations. This notation is shown in eqn [3].

$$G(X) = 0 \qquad [3]$$

where G is a set of nonlinear functions of a vector argument X. The vector argument X can be thought of as consisting of control variables, dependent variables, and fixed parameters. Some examples of the control variables are generator MW output, phase-shifter angles, and generator bus voltages. The dependent variables consist of bus voltage magnitudes and phase angles, as well as the MVAR output of generators performing bus voltage control. Fixed parameters are such items as the reference bus angle, noncontrolled generator MW and MVAR outputs, line parameters, etc.

There are two different algorithms that are commonly used to solve the DPF problem. One is the Newton–Raphson (NR) algorithm and the other is the Fast Decoupled Power Flow (FDPF). Both algorithms will be briefly described in the following sections. The NR algorithm will be described first because the FDPF algorithm is derived from the NR algorithm.

3.15.2.1 NR Algorithm

The basic purpose of the NR algorithm is to solve the SLFEs. These are represented by

$$G(X) = 0 \qquad [4]$$

The solution to these equations is based on the vector matrix Taylor series expansion of $G(X)$ about an initial state. The expansion is

$$G(X) = G(X^0) + J(X - X^0) + \text{higher order terms} \qquad [5]$$

where J is the Jacobian matrix:

$$J = \frac{\partial G(X)}{\partial X} \text{ evaluated at } X = X^0 \qquad [6]$$

The solution process should drive $G(X)$ to zero, so ignoring the higher order terms and letting $\Delta X = X = X^0$ yields

$$-J\Delta X = G(X^0) \qquad [7]$$

This equation is solved iteratively for a series of new states, X^k, until $|G(X^k)| \le \varepsilon$, a prespecified tolerance.

The basic algorithm is as follows:

1. Make an initial guess to the solution X^k with $k = 0$.
2. Evaluate $G(X^k)$. If maximum $|G(X^k)| \le \varepsilon$ then stop.
3. Build and factor J.
4. Solve eqn [7] for $\triangle X$.
5. Update X^k (i.e., $X^{k+1} = X^k + \Delta, k \leftarrow k+1$) and return to Step 2.

3.15.2.2 Fast Decoupled Power Flow Algorithm

The FDPF algorithm is another algorithm that may be used to solve the SLFEs (i.e., $G(X) = 0$). It is derived by making some simplifying approximations to the Jacobian matrix of the NR algorithm that lead to a more computationally efficient algorithm.

The first step in developing the FDPF algorithm is to reorder these equations so that all the real power balance equations are first, followed by the reactive power balance equations. This means that eqn [4] of that section may be rewritten as

$$\begin{bmatrix} \Delta P \\ \Delta Q \end{bmatrix} = \begin{bmatrix} HM \\ JL \end{bmatrix} \times \begin{bmatrix} \Delta\theta \\ \dfrac{\Delta V}{V} \end{bmatrix} \qquad [8]$$

where

ΔP, ΔQ represent the mismatch in the real and reactive power (respectively) that arises from ignoring the higher order terms (i.e., they correspond to $G(X_k)$)
$\Delta\theta, \Delta V/V$ correspond to ΔX
H, M, J, L submatrices which make up the Jacobian matrix.

These submatrices have the following definitions:

$$\begin{aligned} [H] &= \frac{\partial P}{\partial \theta} \\ [M] &= \frac{V\partial P}{\partial V} \approx [0] \\ [J] &= \frac{\partial Q}{\partial \theta} \approx [0] \\ [L] &= \frac{V\partial Q}{\partial V} \end{aligned} \qquad [9]$$

Elements of the off-diagonal submatrices, J and M, are much smaller in magnitude than elements of the diagonal submatrices, H and L, in the matrix equation, because of the weak coupling between the real power and the reactive power equations. Neglecting the off-diagonal coupling submatrices M and J, two sets of matrix equations are obtained:

$$\Delta P = [H] \times [\Delta\theta] \qquad [10]$$

$$\Delta Q = [L] \times \left[\frac{\Delta V}{V}\right] \qquad [11]$$

where $H_{km} = L_{km} = V_kV_m(G_{km}\sin\theta_{km} - B_{km}\cos\theta_{km})$

$$\begin{aligned} H_{kk} &= -B_{kk}V_k^2 - Q_k \\ L_{kk} &= -B_{kk}V_k^2 - Q_k \end{aligned}$$

Further simplifications are made by observing that in most realistic situations

$$\cos\theta_{km} \cong 1 \qquad [12]$$

$$G_{km}\sin\theta_{km} << B_{km} \qquad [13]$$

and

$$Q_k \langle\langle B_{kk} V_k^2 \tag{14}$$

With these approximations, eqns [10] and [11] reduce to

$$[\Delta P] = [VB'V] \times [\Delta\theta] \tag{15}$$

$$[\Delta Q] = [VB''V] \times \left[\frac{\Delta V}{V}\right] \tag{16}$$

where the elements of B' and B'' are based on the branch susceptance terms. Taking the left-most V terms to the left-hand side of the equations and setting the right-most V terms to 1 p.u. in eqn [15], as V affects the MVAR flows mainly, eqns [15] and [16] reduce to

$$\left[\frac{\Delta P}{V}\right] = [B'] \times [\Delta\theta] \tag{17}$$

$$\left[\frac{\Delta Q}{V}\right] = [B''] \times [\Delta V] \tag{18}$$

These equations are the FDPF equations. In calculating the elements of B' and B'', the following decoupling considerations are used: 1.1.1. Shunt elements and off-nominal transformers are neglected in B'; 1.1.2. Phase-shifter angle effects are neglected in B''; 1.1.3. Series resistances are neglected in B''.

The major advantage of these equations is that the matrices $[B']$ and $[B'']$ only need to be calculated and factored once. This gives the FDPF algorithm a speed advantage over the NR algorithm. The basic algorithm for solving these decoupled equations is as follows:

1. Enter with factors of B' and B''. Set ITP and ITQ $= 0$.
2. Compute $\Delta P/V$.
3. If P is not converged, go to Step 5.
4. If Q is converged, go to Step 9.
5. Solve $[B'] \times \Delta\theta = \Delta P/V$, update θ and ITP.
6. Compute $\Delta Q/V$.
7. If Q is converged, go to Step 9.
8. Solve $[B''] \times \Delta V = \Delta Q/V$, update V and ITQ.
9. If P and Q are converged, the solution is reached.
10. If ITP or ITQ exceed the maximum number of iterations, exit unconverged. Otherwise, go to Step 2.

There are a few items that should be noted. First, the simplifying approximations that have been made are only in the linearization of the problem about the initial point. The calculation of the mismatches is performed in detail with no approximations. The algorithm continues to iterate until the solution of $G(X) = 0$ is reached within a prespecified tolerance, usually 0.1 MW. Second, the modeling of control systems and other parameters, such as company interchange control voltage and transformer control, generator voltage-amperes reactive (VAR, unit that measures reactive power) limiting, distributed slack, matrix update, sensitivity calculations, contingency analysis, penalty factor calculation, power transfer distribution factor calculation, etc., are outside the scope of this chapter (Wood and Wollenberg 1984).

3.15.3 The Longer-Term Transmission Grid Problem

3.15.3.1 Problem Overview

There are few in the industry who would argue that the transmission system is currently well positioned to meet the growing demands of the restructured electric power industry. This applies not only to the physical infrastructure of the transmission networks, but also to the control and coordination of system operations.

Restructuring of the industry has fundamentally altered the nature of the electric power business to facilitate large regional competitive wholesale markets. New risk-reward–focused business models introduced to the upstream and downstream power markets provide market incentives beyond the former cost-of-service regulatory approach. At the same time, the continuing development of electric power spot markets has enabled a new breed of power marketers to trade power between low-cost and high-cost markets in response to both short- and long-term supply and demand fluctuations. Because electric power cannot be stored in a massive scale yet, but rather must be produced instantaneously as customers demand it, a robust transmission system is needed to allow these developing wholesale markets to function. These restructuring developments are increasing the reliance of industry – and the consumers that it serves – on the ability of the transmission system to operate dynamically in this new environment and its capability to handle short-term, market-driven power flow changes.

However, recent trends in transmission investment and system operation experience indicate that the transmission sector is not keeping pace with the changing dynamics in the wholesale (and retail) markets (Federal Energy Regulatory Commission 2006). The problem is further magnified with the high penetration of renewable energy in the grid mainly driven by policy mandates. The problems facing the transmission sector are based on two fundamental issues:

- The transmission system was not designed to support market-driven electricity trading and massive penetration of renewable resources into the power system.
- The transmission sector does not provide the incentives needed to support transmission investment and operations improvements necessitated by the changing industry structure and the policy mandates to support environmental goals. These policy mandates are prevalent in various forms in the United States and Europe today, as well as in other parts of the world.

As a result of increased wholesale market trading activity and massive penetration of renewable resources into the power system, we are witnessing the following major changes in the transmission system:

1. The pattern of transmission usage is changing; there is a greater reliance on the capabilities of the transmission grid interconnections between various energy markets.
2. The transmission system is under stress, and transmission expansion has not kept pace with the changes in the interstate electricity marketplace.
3. Transmission investments are lagging (Kaplan 2009).

As noted by the North American Electric Reliability Corporation (NERC), the use of advanced technologies such as superconducting materials, flexible AC transmission systems

(FACTS), or magnetic storage devices could improve transmission transfer capabilities over existing rights of way. However, the current framework does not provide significant incentives for rapid or large-scale transmission research and development initiatives.

The 'reasonable and prudent' stipulation embodied in regulation often requires a lengthy approval process and cost–benefit analyses, increasing the costs of development and delaying the benefits. In addition, to the extent that the introduction of new technology yields significantly increased benefits to system users as compared to conventional technology with similar costs, the transmission owner will not reap greater rewards but will face greater risks, if it pursues new technology under traditional cost-of-service regulation. This will make transmission owners broadly indifferent or even averse to the use of new technology, because they are not rewarded for exceptional performance and innovation.

Furthermore, even though transmission and generation investments are partial substitutes for each other in terms of meeting certain system requirements, generation is not always the most economically efficient means of solving a system problem. To the extent that the transmission system cannot deliver inexpensive electricity, more plants need to be built closer to load centers. Traditionally, in the vertically integrated utility structure, decisions affecting the trade-off between generation and transmission investment fell under a single locus of control, in which decisions were contingent primarily on state regulatory approval and oversight. Although state level regulatory control continues, business decisions concerning investment in these two types of resources under the new functionally unbundled industry structure are often in the hands of separate entities. As discussed, new merchant plants are often located at a distance from their target market, requiring transmission investments to be made even though the supply benefits will be realized elsewhere. The FERC noted this planning problem in Order No. 2000 (FERC Order 2000).

In certain situations, transmission solutions may be more appropriate than increased generation development. Some of the system externalities that may be more appropriately facilitated through transmission investment are the following:

- Expanded market competition through interconnection with multiple supply resources
- Reduced concentration in generation markets through interconnection with multiple supply resources
- Lower overall reserve requirements through access to capacity in neighboring regions
- Improved reactive power management
- Improved voltage stability
- Expanded flexibility in dealing with system emergencies and facilities outages

Although the economic decision between generation and transmission may be relatively clear, the lack of a balanced incentive structure between the generation and transmission sectors, coupled with the fragmentation of system planning among a larger group of market participants and the long schedules for building transmission compared to generation, has significantly tipped the investment balance toward generation.

FERC's Order No. 2000 attempted to rectify this situation. It provided for financial incentives to motivate transmission owners to join RTOs. Among these incentives is the open invitation by the FERC to consider various forms of incentive-based regulation for the transmission sector. This invitation to consider regulatory approaches other than traditional cost-of-service regulation is, in many ways, recognition of the increased risks and problems faced by the transmission sector and the inability of traditional regulation to effectively address these problems.

The emergence of the renewable industry over the last 10 years has further complicated the transmission problem. In many jurisdictions, transmission constraints, especially across market boundaries, or across countries in Europe, have become a major impediment to further penetration of renewable energy into the power system. Although some boundary crossing lines have been built in the past, that experience underscores a number of obstacles such projects face.

FERC's Order No. 1000 (Federal Energy Regulatory Commission 2011) attempts to encourage the development of a market environment that is conducive to the resolution of this problem. Unfortunately, there is too little useful transmission planning at regional, interregional, or interconnection-wide levels; the costs of boundary-crossing projects can be allocated only through project specific negotiations; and the need to obtain construction permits from multiple authorities makes it difficult to site and build boundary crossing lines. Some have argued that the best solution to this suite of problems is to construct a nationwide overlay or 'super-highway' grid (U.S. Department of Energy 2008). Others favor large, discrete transmission projects that connect sizeable renewable resources to major load centers. Still others defend a more conventional buildup of transmission reinforcements – within regions and across multiple regional boundaries – and more use of local renewable resources. Depending on the specific conditions of each project any of these options could provide the optimal outcome.

In the following subsection, we focus on specific major issues that are integral to the longer-term transmission problem.

3.15.3.2 Current Major Transmission Grid Challenges

In this section, we present the key challenges that continue to complicate investments in the transmission grid.

3.15.3.2.1 Transmission Planning

Traditionally, the transmission grid is expanded for reliability or economic reasons. The benefits of reliability are difficult to quantify and are often asserted to be spread over relatively wide areas. Only after reliability planning is complete do planners look for investments that would increase economic efficiency. Economic benefits include reduced network losses and mitigated or eliminated transmission constraints that prevent the use of the lowest-cost set of generators to meet demand. By strengthening the transmission grid, these projects also allow wholesale electricity markets to expand geographically, which mitigates market power and may provide other benefits. Of course, lines justified by economic benefits generally improve system reliability and vice versa (Joskow and Tirole 2005; MIT Study 2011). Recent years have seen very few transmission lines built that had been justified primarily on the basis of economic benefits. However, the emergence of the renewable energy is forcing policymakers and RTOs to create a new category for policy-driven transmission investments to accommodate this type of energy.

The planning process in most RTO regions is significantly more difficult than within vertically integrated utilities because decisions about the installation of new generation are the result of market forces (modified by state and federal support for renewables and other policies) rather than centralized planning. Thus, transmission planning in these regions is subject to additional uncertainties about where future generation may locate and how power will flow around the network, especially when renewable generators are involved. Magnifying this effect are uncertainties regarding future subsidies and requirements for renewable generation, because a painful fact of transmission planning is that it typically takes much longer to plan, get approvals, and build a high-voltage transmission line than a wind farm or solar generating facility. When generator build times are shorter than those for transmission, planners are forced to either anticipate new generation and build potentially unnecessary infrastructure or wait for firm generation plans before starting the process and thereby potentially discourage new generation investment.

Given the large distances required to transfer renewable energy to load centers, consideration of interregional projects one at a time rather than as parts of an interconnection-wide plan is no longer sensible. It has become obvious that making more use of remote renewables in an efficient manner will require permanent planning processes at the interconnection level.

According to FERC Order 2000, the key policy issues that need to be resolved with respect to transmission planning are as follows:

1. *What should be the objectives of the planning process*? For example, planning could be focused on renewable power development or on broader objectives, such as congestion relief and reliability enhancement.
2. *What should be the scope of authority of the planning entities*? Federal transmission planning could be run by interconnection-wide centralized authorities (the top-down approach) or be conducted primarily at a regional level (the bottom-up approach), or as a hybrid.
3. *What is the appropriate scope of the planning process*? Should the planning process extend beyond transmission planning narrowly defined to include a broader array of solutions to power system issues, such as demand response, distributed power, or conventional power plant construction.
4. *Could preferential treatment tied to the planning process distort transmission investment?* The planning proposals typically make available certain benefits, such as a federal permitting option, to projects included in the plan. These benefits could lead developers to add unnecessary features and costs to qualify proposals to meet plan criteria (e.g., proposing only high voltage lines if the plans have a minimum voltage threshold). Avoiding these distortions will require careful oversight or, arguably, limiting the benefits associated with the plan (e.g., putting all new power lines or none, whether or not they are in the plan, under federal government permitting authority).

3.15.3.2.2 Transmission Permitting

Interstate transmission projects require siting permits from every state the line will traverse. If any state disapproves a project, it will at best be delayed for rerouting or at worst canceled. As a result, projects are most vulnerable to challenge and litigation by parties who are not satisfied with the project for any reason. Challenges can take years to resolve. This permitting process has been a major obstacle to transmission investments.

At the federal level, the Energy Policy Act of 2005 gave FERC authority to issue permits for facilities in areas experiencing capacity constraints or congestion and designated by the Secretary of Energy as a National Interest Electric Transmission Corridor (NIETC). These permits would confer rights of eminent domain if a state commission or other entity with authority to approve siting has withheld approval for more than 1 year after the filing of an application seeking approval. However, subsequent Circuit Court decisions made this authority effectively irrelevant, ruling that FERC cannot act if a state simply rejects rather than withholds approval of a project it opposes and that the process to designate NIETCs was flawed. In summary, the parochial interests of the states and localities do not naturally encompass the broader interests of larger regions or of the nation as a whole. Similar policy issues apply to cross border transmission investments in Europe.

The simplest and most elegant solution to the problem of interstate transmission siting is to give FERC authority over significant interstate projects. Legislation should provide clear preemptive backstopping authority for FERC to site a transmission project after it has been approved by a regional planning entity, and a transmission project designated NIETC by Department of Energy (DOE). Legislation for electric transmission comparable to natural gas transmission should be desirable. It is, however, important to recognize that eliminating states' roles entirely has a variety of disadvantages, given their superior knowledge of local conditions (Willrich 2009). Similarly for Europe, we believe that a top-down approach is recommended where an EU authority plans for transmission upgrades across EU member States.

3.15.3.2.3 Transmission Financing and Cost Allocation

The funding of transmission investments unfortunately exhibits some characteristics of the 'chicken and egg' problem, particularly as it applies to renewable energy. Renewable energy plant developers may have difficulty getting funding because the transmission to bring their power output to market is not in place, whereas the transmission projects cannot get loans because the generation that would justify construction of the new lines has not been built. This early funding issue is exacerbated by the typical development pattern for many renewable energy projects. The projects are built in phases over several years. However, it is not economic to build a transmission line in phases; the line must be built at once for the maximum anticipated capacity even if the full load will not be developed until years after the line is first put into operation.

The most contentious transmission financing issue is cost allocation for new interstate transmission lines – that is, deciding which customers pay how much of the cost of building and operating a new transmission line that crosses several states. Clearly, cost allocation is the single largest impediment to any transmission development. Since cost allocation issues affect transmission siting, these two issues must be linked and managed simultaneously. This is an important point, and most current transmission proposals fold the cost allocation issue into the transmission planning process.

A simple way to resolve this problem is to allocate the costs of new projects that are part of an interconnection-wide plan to all customers in the interconnection (sometimes referred to as 'socializing' costs). The idea is that in a synchronized grid all ratepayers benefit to some extent from all transmission system enhancements. A related concept is that new transmission for renewable power yields environmental benefits to all ratepayers. A criticism of interconnection-wide cost allocation is that cost responsibility arguably becomes more diffuse and the incentives for cost discipline decline. Another criticism is that especially favorable funding for transmission could bias policymakers and investors away from other solutions to electric market problems, such as demand response or local renewable power. Other cost allocation approaches are being explored across the country but no approach is standard or even widely used (FERC Order 2000).

In summary, state and federal regulatory agencies should continue to authorize for proposed transmission projects rates of return on capital sufficiently high to attract financing from their traditional sources. Under normal conditions, the capital required to expand and modernize America's transmission grid may be attracted from the private sector. This assumes, however, a rational policy framework exists for planning, cost recovery and allocation, and siting of electric transmission facilities. Investor-owned utilities with strong balance sheets and independent transmission companies with requisite financial capacity should all play important roles in developing, financing, and owning the infrastructure.

3.15.4 Incentives for Transmission Investments

In this chapter, we present and analyze the risks transmission owners encounter in the restructured electric power industry and evaluate the potential for the emergency of merchant transmission grid expansions. In particular, we analyze the incentives financial transmission rights provide for the development of merchant transmission grid expansions.

3.15.4.1 Introduction

Just as restructuring of the electric power industry has increased and changed the risk profile of the predominantly deregulated wholesale and retail market participants, restructuring has also altered the risk profile of transmission owners. As regulated businesses, the increase in risk has not been as great for transmission owners as it has been for those upstream and downstream businesses more directly exposed to market forces. Nevertheless, risks do exist, including the following:

- **Financial strength** – Unbundled transmission entities are financially smaller than the former vertically integrated utility of which they were once a part.
- **Revenue diversity** – Transmission entities are largely dependent on a single revenue stream coming from their transmission assets, in contrast to a larger diversified stream of revenue derived from the combined generation, transmission, and distribution activities of the former vertically integrated utility. This reliance on a single revenue stream, though regulated, still places greater risks on the transmission owner.
- **Increased system demands** – Transmission owners and operators need to spend considerably more time optimizing the operation and maintenance of their transmission assets to facilitate the rapid growth in wholesale trading. This increasing reliance on the efficient operation of the transmission system under demanding conditions increases the system performance risks faced by the transmission owners and operators.
- **Increased market uncertainty** – The lack of a defined end-state configuration for the transmission sector in the restructured environment increases the uncertainty for transmission owners contemplating investments. Uncertainty over such issues as changing usage patterns arising from the continuing evolution of the wholesale and retail electricity markets and the high penetration of renewable energy could make seemingly sound investments today less valuable than anticipated in the future. Under-utilization of investments in the transmission grid poses a real threat to transmission investors and new methodologies are needed to ensure that this problem is mitigated.
- **Competitive threats** – Stand-alone transmission entities will face increased competitive threats, such as those from merchant transmission development and distributed generation. Given the mismatch between committing to long-lived (e.g., 40–50 years) investments to satisfy customer requests without similar length customer contracts, transmission owners are exposed to significant risks. It is tempting to say that this does not matter, because a regulated entity can just roll-in any such 'orphaned' costs and recover them through higher rates for the remaining customers. However, such actions will require increasing prices and could harm a company's competitive position.
- **Counterparty risk** – The growth of competition in the wholesale and retail electricity markets results in an expanding and changing variety of traders, marketers, aggregators, and other market participants requesting transmission service. This rapid increase in the number and diversity of transmission customers exposes transmission owners to increased counterparty financial risks that were not as prevalent for formerly vertically integrated utilities.
- **Increased regulatory uncertainty** – Significant uncertainty exists over the future regulatory rules for transmission. As we discussed earlier, it is imperative that a new framework of transmission investments is implemented where the key challenges of transmission planning, transmission permitting and siting, and financing and cost allocation are effectively addressed.

Whereas the risk profile for transmission owners and operators has increased, the reward structure has changed very little. Cost-of-service regulation still persists for almost every transmission owner in the United States. Although an increase in the allowed rate of return on transmission investment is not the sole solution to the industry's problems, it would signify the recognition of the increased risks faced by transmission owners. Increasing the allowed rate of return, either on new investment or the entire rate base, will improve the investment incentives for transmission owners, but it does not provide the necessary incentives for performance or customer service improvement. To address these issues, a new regulatory approach that provides incentives for both investment and performance improvement should be widely used.

However, as part of the regulatory framework there is room for merchant transmission additions within regional transmission systems, that is, transmission additions executed by private market participants. To the extent that the actual market-based cost/benefit of an interconnection is not appropriately reflected through the existing regulatory model, the construction of that asset as a merchant facility may be a way to overcome this regulatory gap and satisfy customer demand. Benefits to system users increase with greater coordination of transmission maintenance, investment, and other decisions affecting system availability and operation. This is one of the principal tenets behind the FERC movement to group transmission owners into large-scale RTOs: The larger the area under a single locus of control, the easier it will be to facilitate markets and deliver benefits to customers. Several researchers have argued that, under a stringent set of assumptions, the merchant investment model has a remarkable set of attributes that appear to solve the natural monopoly problem and the associated need for regulating transmission companies traditionally associated with electric transmission networks (Joskow and Tirole 2005). However, in practice, the merchant transmission model has not received substantial traction.

3.15.4.2 FTRs and Incentives for Expansion of the Transmission Grid

In principle, nobody should invest in grid expansions just to obtain rights to congestion rentals on the resulting additional capacity. Given the large economies of scale in grid investments, the principal effect of grid investments is to reduce or eliminate congestion rents. Additionally, the principal reason anybody would agree to pay part of the cost of a grid expansion is to create lower congestion charges for itself, which implies lower, not higher, congestion rents for the system. Thus, allocating Financial Transmission Rights (FTRs) to those who pay for a grid expansion will at best provide a minor increase in the incentive (or decrease in the disincentive) to join any coalition proposing to pay for a grid expansion.

Resolution of the inherent conflict between FTR holders and future investments could possibly be achieved by proper coordination between transmission expansion and the FTR auction timeline. A new transmission facility for example should not be made available before the currently effective FTRs expire so that there will not be an impact on the FTR value. The reduced value of FTRs due to the transmission expansion will then be reflected in the next FTR auction and there will be no damage to FTR holders.

Another related issue is the compensation to the investors that sponsor the transmission expansion. It is proposed that the investors will receive FTRs on the new transmission facilities. However, once new facilities are in place, the value of these FTRs may be substantially reduced. Therefore, the motivation for market forces in transmission expansion may become questionable. Furthermore, transmission expansion will usually benefit many more market participants than the investors, even participants that enter into the market after completion of the project. How can the costs and benefits of transmission expansion be allocated equitably? A regulatory backstop is required to manage a large project and allocate its costs to all users, if market forces fail to sort out all problems. If the project also benefits consumers, it is important to make distribution companies pay part of the costs, which, in turn, would add these costs to the distribution charges paid by customers.

3.15.4.3 Final Thoughts on Merchant Transmission Grid Expansions

The main issue related to merchant transmission grid expansions is the development of a regulatory system that fosters merchant transmission, who should pay for it, how much of it each will own, and how its cost will be recovered from future uses. Letting prospective alliances bid for a piece of the project based on their willingness to take risks on future usage is an idea worth trying – although adding FTRs to the process may not accomplish much, for the reasons outlined above. This process cannot provide a perfect solution to the problems of free riders and to the uncertainty about future usage. Nevertheless, there are no perfect solutions to these fundamental problems, and some version of this proposal may be feasible.

Unfortunately, where grid investments are concerned, there may be no good alternative to maintaining a significant role for central planning and regulation. The objective of minimizing central planning and regulatory intervention in the market is understandable and commendable. Unfortunately, markets work badly when externalities are large and property rights are poorly defined, as they inherently are on an electricity grid. New, sophisticated theories and systems, such as identification of the most significant congested paths and frequent updating of these paths because of system configuration changes, can be used to create property rights and internalize externalities, so that the role of the market can be safely expanded and the role of regulated central planning can be reduced. However, it can be dangerous to roll back planning and regulation too far before putting good market processes in place.

3.15.5 A Vision for Transmission

The uncertainties, risks, and challenges with respect to transmission grid investments presented in Section 3.24.4 have resulted in under-investment in the transmission infrastructure in many parts of the world. Clearly, the evolution of the transmission grid is not keeping up with the rapid changes in the generation sector. An additional major challenge transmission operators and planners need to deal with in the future is related to the vulnerabilities of the transmission grid owing to climate variability.

Climate vulnerabilities are mainly associated with the frequency and strength of weather extremes. The transmission grids are vulnerable to extreme events like flooding whereby cable networks or pipelines can be broken due to land erosion. Also, high amounts of snow can result in the overloading of electrical transmission lines, which therefore can be broken. Similar results are associated with falling trees caused by snow, high winds, or land erosion by the water streams. Strong winds at specific locations (e.g., gorges) can create vibration in the lines that may result in serious problems. Transmission lines near the coastlines are vulnerable to sea salt deposition that reduces the resistance with a potential of leaking and sparking. Furthermore, transmission lines are exposed to serious damage from overloading in case of heat waves. Any perturbation in weather conditions, and especially extreme weather conditions, can increase/decrease the vulnerability of the transmission grid. Substantial investment in the transmission infrastructure and sophisticated communication technologies, along with sound regulatory policies, are required to ensure the development of a robust transmission grid that can effectively address the challenges of rapidly changing energy sector.

Furthermore, the successful restructuring of the electric power industry in the United States and around the world depends, in large part, on the ability of the transmission sector to evolve and address the emerging problems facing the energy sector. These problems call for sound and bold implementation of innovative regulatory solutions and new business structures. The establishment of effective incentive regulation, coupled with unequivocal support for the development of for-profit transmission entities, offers the best solution to the mounting problems within the transmission sector. The additional revenues allowed to transmission entities for superior performance under such properly designed and implemented incentive plans would be more than repaid in cost savings and service benefits for electricity consumers. Consumers will benefit in several ways from a hybrid model of infrastructure development in which regulated and merchant transmission investments have an important role to play in securing a robust transmission sector. Even though the sector is not in crisis, major improvements in the regulatory and technological front are needed.

Resolution of the key challenges such as transmission planning, permitting and siting, and cost allocation will greatly contribute to sound transmission investments that can lead to:

1. Lower prices
2. Improved service and reliability
3. Balancing economically efficient investment decisions between transmission and generation
4. Adoption of new technologies

It is important to note that we should be concerned much more about under-investment in transmission than with overinvestment, because the societal costs of under-investment in transmission are much larger than the societal costs of overinvestment. External factors, such as licensing requirements, the need for rights of way, and 'not in my back yard' opposition to transmission infrastructure, already place significant constraints on overinvestment in major new transmission projects.

The transmission grid of the future will look very different than that of the past. The transmission grid of the past was built for a specific business and technical model: Power plants would use transmission lines to move electricity to distribution networks for delivery to customers. The power plants were large, central station facilities using fossil, nuclear, or hydroelectric energy sources, and were designed to run as-needed, when-needed. The power flow was one way, from the power plant to the customer. This model is already changing in major ways because of (1) variable renewable generation, (2) demand response, and (3) distributed generation. A key characteristic of these developments is potentially less predictability (in respect to availability and level of service) than traditional resources. The evolution of the current transmission model to an infrastructure with 'smart grid' capabilities is required to address these challenges.

The smart grid involves the integrated operation of the power system from the home to the power plant. It will provide improved real-time transmission monitoring and reliability and consumer energy management (FERC Order 2000). The transmission monitoring includes real-time monitoring of grid functions, improved automated diagnosis and responses to grid failure, 'plug and play' ability, and enhanced ability to manage high penetration of renewable energy into the grid. The consumer energy management, via the Advanced Metering Infrastructure (AMI), includes a two-way communication between the customer and the utility, ability to respond to high prices through links between the smart meter and the consumer's appliances, automated fault detection, easier management of distributed generation, and effective management of millions of connections of plug-in hybrid electric vehicles into the transmission grid. Finally, the smart grid is considered essential in managing the transition to a low-carbon economy and the successful implementation of sound environmental policies.

It is important also to mention that much opportunity for innovation remains on the demand side beyond smart meters and device-level price signaling. Microgrid distribution architectures of the future will require a finer level of coordination between power consuming devices and the transmission grid. This coordination will become possible as high speed networks such as Internet broadband and 4G cellular communications become universal and will involve devices with WiFi connectivity. This is what is known in high-tech circles as "the Internet of Things." These technologies will allow distributed generation resources across large populations of local wind and solar resources to be coordinated en masse, while ensuring local transmission and distribution constraints are met. The imprecise demand response programs of today will evolve to sophisticated network access control protocols analogous to those that govern communications devices that access wired networks and wireless spectrum such as Ethernet and Code Division Multiple Access (CDMA). Wide-scale distributed demand-side machine intelligence based on distributed computing-based stochastic control algorithms have recently been developed that provide fast and precise control over aggregate demand without significantly inconveniencing individual consumers (Ranade and Beal 2010). These innovations will result in a transmission grid architecture transformed from today's central generation and distribution 'fan' model to one where demand information flows upstream from end consumers to the grid operators and utilities. This transmission grid architecture will allow for a more self-organized, flattened, microgrid-based network model similar to the Internet to evolve.

In summary, the following recommendations are considered essential for the adoption of coherent and stable national policies on greenhouse gas emissions, electric vehicles, demand response, and renewable and distributed generation. These recommendations would enhance investment incentives and thereby accelerate the appropriate evolution of the grid.

1. Continue to support organized wholesale electricity markets along with open, nondiscriminatory access to the transmission grid.
2. Implement new legislation to grant FERC enhanced siting authority for major transmission facilities that cross state boundaries.
3. Implement a sound framework for addressing transmission planning, permitting, and cost allocation issues.
4. Encourage the implementation of the smart grid and various technologies that allow two-way communications between the grid operators/utilities and the customer devices.
5. Implement new emerging demand response management technologies that will allow for the emergence of flexible demand to be curtailed when necessary in the mass market.
6. Encourage R&D for the development and implementation of new algorithms, methodologies, software, and communication systems into the transmission grid operations.
7. Implement better methods and tools for the collection and dissemination of transmission data.

Appendix A Fundamentals: Concepts of Electric Power Systems

An electric power industry is composed of three basic components: generation, which converts primary energy resources into electricity; distribution, which distributes electricity to millions of consumers at home, work, and play; and transmission, which connects generators to distributors. Among modern, industrially advanced nations, America's electric power industry is unique. It is largest in size, with about 1 000 000 MW of generating capacity, serving the largest economy in the world. To understand electric power systems, it is helpful to have a basic understanding of the fundamentals of electricity. These include the concepts of energy, voltage, current, direct current (DC), alternating current (AC), impedance, and power. The remainder of this section presents these basic concepts (Blume 2007).

A.1 Energy

Energy is the ability to perform work. Energy cannot be created or destroyed but can be converted from one form to another. For example, chemical energy in fossil fuels can be converted into electrical energy, and electrical energy in turn can be converted into useful work in the form of heat, light, and motion. Energy is measured in watt-hours (Wh) and for larger values is expressed in kilowatt (thousand watt, kW), megawatt (million watt, MW), gigawatt (billion watt, GW), or terawatt (trillion watt, TW) hours.

A.2 Voltage

Voltage (also referred to as potential) is measured between two points and is a measure of the capacity of a device connected to those points to perform work per unit of charge that flows between those points. Voltage can be considered analogous to the pressure in a water pipe. Voltage is measured in volts (V), and for large values expressed in kilovolts (kV) or megavolts (MV).

A.3 Current

Current is a measure of the rate of flow of charge through a conductor. It is measured in amperes (A). Current can be considered analogous to the rate of flow of water through a pipe. Current can be unidirectional, referred to as 'direct current,' or it can periodically reverse directions with time, in which case it is called 'alternating current.' Voltage also can be unipolar – in which one point is always at a higher voltage than the other – or alternating in polarity with time. Unipolar voltage is referred to as 'DC voltage' as in Figure 2.

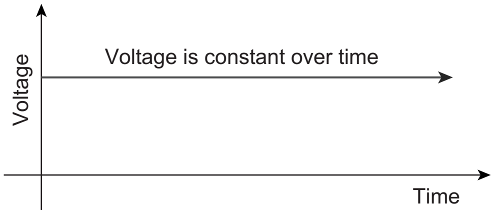

Figure 2 Direct current (DC voltage). Steven Blume, "Electric Power System Basics," IEEE Press Series on Power Engineering, Wiley 2007, a John Wiley & Sons, Inc. Publication.

Voltage that reverses polarity in a periodic fashion is referred to as "AC voltage" as in Figure 3.

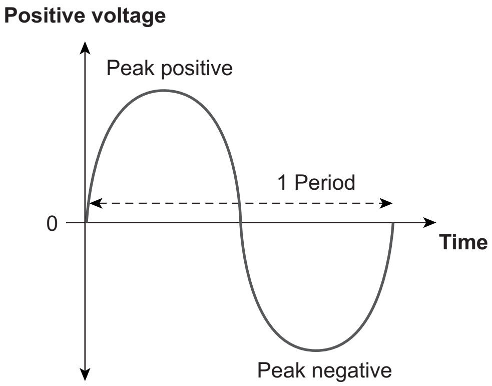

Figure 3 Alternating current (AC voltage). Steven Blume, "Electric Power System Basics," IEEE Press Series on Power Engineering, Wiley 2007, a John Wiley & Sons, Inc. Publication.

Alternating currents and voltages in power systems have nearly sinusoidal profiles. AC voltage and current waveforms are defined by three parameters: amplitude, frequency, and phase. The maximum value of the waveform is referred to as its 'amplitude.' Frequency is the rate at which current and voltage in the system oscillate, or reverse direction and return. Frequency is measured in cycles per second, also called 'hertz' (Hz). In the United States, as well as the rest of North America and parts of South America and Japan, the AC system frequency is 60 Hz, whereas in the rest of the world it is 50 Hz. DC can be considered a special case of AC, one with frequency equal to zero. The phase of an AC waveform is a measure of when the waveform crosses zero relative to some established time reference. Phase is expressed as a fraction of the AC cycle and measured in degrees (ranging from -180 to $+180°$). There is no concept of phase in a DC system.

A.4 Impedance

Impedance is a property of a conducting device – for example, a transmission line – that represents the impediment it poses to the flow of current through it. The rate at which energy flows through a transmission line is limited by the line's impedance. Impedance has two components: resistance and reactance. Impedance, resistance, and reactance are all measured in ohms.

A.5 Power

Power is the rate at which energy is flowing or work is being done. Because voltage is the amount of work done for each unit of charge that flows and current is the rate of flow of charge, the product of voltage and current is the rate of work – power, or more precisely instantaneous power. Because power loss is equal to the resistance of a conductor times the square of the current, loss in a transmission line can be reduced by increasing the transmission voltage, which allows the current to be reduced for the same amount of power transmitted. As a result, long transmission lines employ high voltage. However, high-voltage lines also have drawbacks, including the need to maintain larger clearances to maintain safety.

In AC systems, wherein voltage and current oscillate many times a second, the instantaneous power they produce is also rapidly varying. Negative instantaneous power is equivalent to power flowing in the backward direction. In electric power systems, it is more valuable to have measures of power that are averages over many cycles. These measures are real power, reactive power, and apparent power. Only two of these three measures are independent; apparent power can be determined from real power and reactive power.

Real power, also called 'active power' or 'average power,' is the average value of instantaneous power and is power that actually does work. It is measured in watts. Although instantaneous power can be flowing in both directions, real power only flows in one direction. Real power is zero if the phase difference between voltage and current is 90°.

If the voltage and current waveforms are 'in phase' – that is, they cross zero at the same time – then instantaneous power, although varying, is always positive or flowing in one direction. In this case, all the power is real power. However, if one waveform is shifted in time relative to the other, a condition called 'out of phase,' then power takes on both positive and negative values, as shown. This phase difference can arise, for example, because of the reactance of the transmission line. Here, in addition to the real power that is flowing in one direction, there is back and forth movement of power called 'reactive power.' While it does no useful work, reactive power flow still causes power losses in the system because current is flowing through components, such as transformers and transmission lines, which have resistance. Reactive power is measured in volt-amperes reactive (VAR).

Appendix B Electric Power System Structure

The electric power system consists of generating units where primary energy is converted into electric power, transmission and distribution networks that transport this power, and consumers' equipment (also called 'loads') where power is used. Although originally generation, transport, and consumption of electric power were local to relatively small geographic regions, today these regional systems are connected together by high-voltage transmission lines to form highly interconnected and complex systems that span wide areas. This interconnection allows economies of scale, better utilization of the most economical generators, increased reliability, and an improved ratio of average load to peak load due to load diversity, thus increasing capacity utilization. Interconnection also leads to complexity, however, as any disturbance in one part of the system can adversely impact the entire system (Blume 2007). We discuss each of its subsystems next.

B.1 Generation

Electric power is produced by generating units, housed in power plants, which convert primary energy into electric energy. Primary energy comes from a number of sources, such as fossil fuel and nuclear, hydro, wind, and solar power. The process used to convert this energy into electric energy depends on the design of the generating unit, which is partly dictated by the source of primary energy. The term 'thermal generation' commonly refers to generating units that burn fuel to convert chemical energy into thermal energy, which is then used to produce high-pressure steam. This steam then flows and drives the mechanical shaft of an AC electric generator that produces alternating voltage and current, or electric power, at its terminals. These generators have three terminals and produce three AC voltages, one at each terminal, which are 120° out of phase with respect to each other.

From the operational perspective of the electric power system, generating units are classified into three categories: base-load, intermediate, and peaking units. Base-load units are used to meet the constant, or base, power needs of the system. They run continuously throughout the year except when they have to be shut down for repair and maintenance. Nuclear and coal plants are generally used as base-load units, as are run-of-the-river hydroelectric plants. Intermediate units, also called cycling units, operate for extended periods of time but, unlike base-load units, not at one power continuously. They have the ability to vary their output more quickly than base-load units. Combined-cycle gas turbine plants and older thermal generating units generally are used as intermediate units. Peaking units operate only when the system power demand is close to its peak. They have to be able to start and stop quickly, but they run only for a small number of hours in a year.

Large generating units generally are located outside densely populated areas, and the power they produce has to be transported to load centers. They produce three-phase AC voltage at the level of a few to a few tens of kV. To reduce power losses during onward transmission, this voltage is immediately converted to a few hundred kV using a transformer. All the generators on a single AC system are synchronized. In addition to the main large generating units, the system typically also has some distributed generation, including combined heat and power units. These and other small generating units, such as small hydroelectric plants, generally operate at lower voltages and are connected at the distribution system level. Small generating units, such as solar photovoltaic arrays, may be single phase.

B.2 Transmission

The transmission system is the most complex machine man ever built. It carries electric power over long distances from the generating units to the distribution system. The transmission network is composed of power lines and stations/substations. Transmission system power lines, with rare exceptions, are attached to high towers. However, in cities, where real estate is valuable, transmission lines are sometimes made up of insulated cables buried underground. Stations and substations house transformers, switchgear, measurement instrumentation, and communication equipment. Transformers are used to change the level of the transmission voltage. Switchgear includes circuit breakers and other types of switches used to disconnect parts of the transmission network for system protection or maintenance. Measurement instrumentation collects voltage, current, and power data for monitoring, control, and metering purposes. Communication equipment transmits these data to control centers and also allows switchgear to be controlled remotely. Because transmission networks carry power over long distances, the voltage at which they transmit power is high to reduce transmission losses, limit conductor cross-sectional area, and require narrower rights-of-way for a given power. However, to maintain safety, high-transmission voltages require good insulation and large clearance from the ground, trees, and any structures.

Transmission voltages vary from region to region and country to country. The transmission voltages commonly (but not exclusively) used in the United States are 138, 230, 345, 500, and 765 kV. A voltage of 1000 kV has been used on a transmission line in China. Although most transmission is three phase AC, for very-long-distance transmission, High Voltage Direct Current (HVDC) can be beneficial because transmission lines present no reactive impedance to DC. HVDC also only requires two conductors instead of three. However, HVDC transmission lines require expensive converter stations (utilizing power electronics technology) at either end of the line to connect to the rest of the AC system.

Transformers at transmission substations convert transmission voltages down to lower levels to connect to the sub-transmission network or directly to the distribution network. Subtransmission carries power over shorter distances than transmission and is typically used to connect the transmission network to multiple nearby relatively small distribution networks. In the United States, the commonly used sub-transmission voltages are 69 and 115 kV.

The power that can be transmitted on a transmission line is limited by either thermal, voltage stability, or transient stability constraints, depending on which is the most binding. The thermal constraint arises because of the resistance of the transmission line that causes excessive power losses and hence heating of the line when the power flowing through it exceeds a certain level. The voltage stability constraint arises because of the reactance of a transmission line that causes the voltage at the far end of the line to drop below an allowable level (typically 95% of the nominal design voltage level) when the power flowing through the line exceeds a certain level. The transient stability constraint relates to the ability of the transmission line to deal with rapid changes in the power flowing through it without causing the generators to fall out of synchronism with each other. Generally, maximum power flow on short transmission lines is limited by thermal constraints, while power flow on longer transmission lines is limited by either voltage or transient stability constraints. These power flow constraints cause so-called congestion on transmission lines, when the excess capacity in the lowest-cost generating units cannot be supplied to loads due to the limited capacity of one or more transmission lines. Some very large consumers take electric power directly from the transmission or sub-transmission network. However, the majority of consumers get their power from the distribution network.

B.3 Distribution

Distribution networks carry power the last few miles from transmission or sub-transmission to consumers. Power is carried in distribution networks through wires either on poles or, in many urban areas, underground. Distribution networks are distinguished from transmission networks by their voltage level and topology. Lower voltages are used in distribution networks, as lower voltages require less clearance. Typically, lines up to 35 kV are considered part of the distribution network. The connection between distribution networks and transmission or subtransmission occurs at distribution substations. Distribution substations have transformers to step voltage down to the primary distribution level (typically in the 4–35 kV range in the United States). Like transmission substations, distribution substations also have circuit breakers and monitoring equipment. However, distribution substations are generally less automated than transmission substations.

Distribution networks usually have a radial topology, referred to as a "star network," with only one power flow path between the distribution substation and a particular load. Distribution networks sometimes have a ring (or loop) topology, with two power flow paths between the distribution substation and the load.

B.4 Load

Electricity is consumed by a wide variety of loads, including lights, heaters, electronic equipment, household appliances, and motors that drive fans, pumps, and compressors. These loads can be classified based on their impedance, which can be resistive, reactive, or a combination of the two. In theory, loads can be purely reactive, and their reactance can be either inductive or capacitive. However, in practice the impedance of most loads is either purely resistive or a combination of resistive and inductive reactance. Heaters and incandescent lamps have purely resistive impedance, whereas motors have impedance that is resistive and inductive. Purely resistive loads only consume real power. Loads with inductive impedance also draw reactive power. Loads with capacitive impedance supply reactive power. Because of the abundance of motors connected to the network, the power system is dominated by inductive loads. Hence, generating units have to supply both real and reactive power. Because capacitors produce reactive power, they often are connected close to large inductive loads to cancel their reactive power (i.e., increase the effective power factor of the load) and reduce the burden on the network and the generators. From the power system's operational perspective, the aggregate power demand of the loads in a region is more important than the power consumption of individual loads. This aggregate load is continuously varying.

Appendix C Fundamentals of Transmission Networks

C.1 Overview

High-voltage transmission lines transport power over long distances much more efficiently than lower-voltage distribution lines for two main reasons. First, high-voltage transmission lines take advantage of the power equation, that is, power is equal to the voltage times current. Therefore, increasing the voltage allows one to decrease the current for the same amount of power. Second, since transport losses are a function of the square of the current flowing in the conductors, increasing the voltage to lower the current drastically reduces transportation losses. Plus, reducing the current allows one to use smaller conductor sizes. Therefore, we increase the voltage to reduce the current and the losses (Blume 2007).

A typical high-voltage transmission line is a three-phase 500 kV transmission line with two conductors per phase. The two-conductors-per-phase option is called *bundling*. Power companies bundle multiple conductors – double, triple, or more – to increase the power transport capability of a power line. The type of insulation used in this line is referred to as *V-string* insulation. V-string insulation, compared with *I-string* insulation, provides stability in wind conditions. This line also has two *static wires* on the very top to shield itself from lightning. The static wires in this case do not have insulators; instead, they are directly connected to the metal towers so that lightning strikes are immediately grounded to earth. Hopefully, this shielding will keep the main power conductors from experiencing a direct lightning strike.

Transmission lines can be built overhead or underground. Underground transmission is usually 3–10 times more costly than overhead transmission owing to right of way requirements, obstacles, and material costs. It is normally used in urban areas or near airports where overhead transmission is not an option.

Also DC transmission systems are sometimes used for economic reasons, system synchronization benefits, and power flow control. In this case, the three-phase AC transmission line is converted into a two-pole (plus and minus) DC transmission line using bidirectional rectification *converter stations* at both ends of the DC line. The converter stations convert the AC power into DC power and vice versa. The reconstructed AC power must be filtered for improved power quality performance before being connected to the AC system. DC transmission lines do not have phases; instead, they have positive and negative *poles*. There are no synchronization issues with DC lines. The frequency of DC transmission is zero and, therefore, there are no concerns about variations in frequency between interconnected systems. A 60-Hz system can be connected to a 50-Hz system using a DC line. For economic reasons, a DC line may have advantages over the AC line, because the DC lines have only two conductors versus three conductors in AC lines. The overall cost to build and operate a DC line, including converter stations, may cost less than an equivalent AC line owing to the savings from one less conductor, narrower right of ways, and less expensive towers.

The major types of equipment found in most transmission and distribution substations are presented next. Detail exhibition of the purpose, function, design characteristics, and key properties of each equipment is outside the scope of this chapter. The substation equipment includes (1) transformers, (2) regulators, (3) circuit breakers and reclosers, (4) air disconnect switches, (5) lightning arresters, (6) electrical buses, (7) capacitor banks, (8) reactors, (9) static var compensators, (10) control building, and (11) preventative maintenance equipment. We'll close this section with a brief summary of conductors and conductor types and sizes.

C.2 Conductors

Conductor material (all wires), type, size, and current rating are key factors in determining the power handling capability of transmission lines, distribution lines, transformers, service wires, and so on. A conductor heats up when current flows through it owing to its resistance. The resistance per mile is constant for a conductor. The larger the diameter of the conductor, the less resistance there is to current flow. The amount of current that causes the temperature to rise depends on the conductor material and size. The conductor type determines its strength and application in electric power systems.

Utility companies use different conductor materials for different applications. Copper, aluminum, and steel are the primary types of conductor materials used in electrical power systems. Other types of conductors, such as silver and gold, are actually better conductors of electricity; however, cost prohibits wide use of these materials.

C.3 Conductor Types and Size

Power line conductors are either solid or stranded. Rigid conductors such as hollow aluminum tubes are used as conductors in substations because of the added strength against sag in low-profile substations when the conductor is only supported at both ends. Rigid copper bus bars are commonly used in low-voltage switchgear because of their high current rating and relatively short lengths. The most common power line conductor types are (1) solid, (2) stranded, and (3) aluminum conductor, steel-reinforced (ACSR). With respect to the size, there are two conductor size standards used in electrical systems. One is for smaller conductor sizes (American Wire Gauge) and the other is for larger conductor sizes (circular mils).

EDITOR-IN-CHIEF

Dr Roger A. Pielke is currently a senior research scientist in CIRES and a senior research associate at the University of Colorado-Boulder in the Department of Atmospheric and Oceanic Sciences (ATOC) at the University of Colorado in Boulder (November 2005—Present). He is also an emeritus professor of atmospheric science at Colorado State University and has a 5-year appointment (April 2007—March 2012) on the Graduate Faculty of Purdue University in West Lafayette, Indiana.

He has studied terrain-induced mesoscale systems, including the development of a three-dimensional mesoscale model of the sea breeze, for which he received the NOAA Distinguished Authorship Award for 1974. He has worked for NOAA's Experimental Meteorology Lab (1971—74), The University of Virginia (1974—81), and Colorado State University (1981—2006). He served as Colorado State Climatologist from 1999—2006. He was an adjunct faculty member in the Department of Civil and Environmental Engineering at Duke University in Durham, North Carolina (July 2003—06). He was a visiting professor in the Department of Atmospheric Sciences at the University of Arizona from October to December 2004.

He has served as chairman and member of the AMS Committee on Weather Forecasting and Analysis, and was the chief editor for the Monthly Weather Review for 5 years from 1981 to 1985. In 1977, he received the AMS Leroy Meisinger Award for 'fundamental contributions to mesoscale meteorology through numerical modeling of the sea breeze and interaction among the mountains, oceans, boundary layer, and the free atmosphere'. He received the 1984 Abell New Faculty Research and Graduate Program Award, and also received the 1987/1988 Abell Research Faculty Award. He was declared 'Researcher of the Year' by the Colorado State University Research Foundation in 1993. In 2000, he received the Engineering Dean's Council Award from Colorado State University.

He authored a book published by Academic Press entitled 'Mesoscale meteorological modeling' in 1984 with a 2nd edition in 2002, a book for Routledge Press entitled 'The Hurricane in 1990, a book (coauthored with W.R. Cotton) for Cambridge Press entitled 'Human impacts on weather and climate in 1995; 2nd ed., 2006, a book (coauthored with R.A. Pielke, Jr.) entitled 'Hurricanes: Their nature and impacts on society' published in 1997 by John Wiley and Sons, and was co-chief editor (with R.A. Pielke, Jr.) of a book entitled 'Storms' published by Routledge Press in 1999.

He was elected as a fellow of the AMS in 1982 and fellow of the American Geophysical Union in 2004. From 1993—96, he served as editor-in-chief of the US National Science Report to the IUGG (1991—94) for the American Geophysical Union. From January 1996 to December 2000, he served as co-chief editor of the *Journal of Atmospheric Science*. In 1998, he received NOAA's ERL Outstanding Scientific Paper (with Conrad Ziegler and Tsengdar Lee) for a modeling study of the convective dryline. He was designated a Pennsylvania State Centennial Fellow in 1996, and named the Pennsylvania State College of Earth and Mineral Sciences Alumni of the year for 1999 (with Bill Cotton). He is currently serving on the AGU Focus Group on Natural Hazards (August 2009—Present) and the AMS Committee on Planned and Inadvertent Weather Modification (October 2009—Present). He is among one of three faculties and one of four members listed by ISI Highly Cited in Geosciences at Colorado State University and the University of Colorado at Boulder, respectively.

He has published over 370 papers in peer-reviewed journals, 55 chapters in books, coedited 9 books, and made over 700 presentations during his career to date. The listing of papers can be viewed at the project website: http://cires.colorado.edu/science/groups/pielke/pubs/. He also launched a science weblog in 2005 to discuss weather and climate issues. This weblog was named one of the 50 most popular Scienceblogs by Nature Magazine on 5 July 2006 and is located at http://pielkeclimatesci.wordpress.com/.

VOLUME EDITORS

Dr Jimmy Adegoke is an award winning climate scientist whose research focuses on understanding the relationships between changing land surface processes and diverse indicators of environmental change. His recent work focuses on societal impacts of environmental change including air pollution studies in rapidly changing midlatitude urban areas and climate impacts on water resources in the Lake Chad Basin. He teaches at the University of Missouri-Kansas City (UMKC) where he served as chair of the Department of Geosciences from 2008—10. From August 2010 until very recently, he was Executive Director of the Council for Scientific and Industrial Research (CSIR) Natural Resources and Environment (NRE) Division, Pretoria, South Africa where he also served as the Director of the Applied Center for Climate and Earth Systems Science (ACCESS), a Center of Excellence (CoE) of the South Africa Department of Science and Technology (DST) Global Change Grand Challenge (GCGC) program. He is a member of several professional societies including the American Geophysical Union (AGU), Association of American Geographers (AAG), and American Meteorological Society (AMS). He is on the advisory council of the African Association for Remote Sensing of the Environment (AARSE) and also serves on the technical advisory committee of several United Nations applied science programs, including the United Nations Educational Scientific and Cultural Organization (UNESCO) crosscutting project on the application of remote sensing for water resources and ecosystem management in Africa. He lives in Kansas city where he served a 3-year team as an appointee of the Mayor of Kansas City Missouri (KCMO) on the city's Environmental Management Commission (EMC).

Dr Caradee Y. Wright is a senior researcher at the Council for Scientific and Industrial Research in the Climate Studies, Modelling and Environmental Health Research Group, leading the environmental health research team. She holds a PhD in public health from the University of Otago and an MSocSc in geography and environmental management from the University of Natal. Her research focuses on personal solar ultraviolet radiation exposure, personal dosimetry, health risk assessment, and skin cancer prevention. Recently, she has also worked in the field of air quality and finding ways to integrate public health into air quality management. She also works in the broader field of environmental health, leading large epidemiological, cross-sectional community surveys to consider the impacts of environmental pollution on community health and appropriate interventions. She is cochair of the South African Young Academy of Science, a member of the Global Young Academy, a council member of the National Association for Clean Air, and founder of the Environmental Health Research Network. In 2012, she was named one of 200 top young South Africans for her efforts to establish a SunSmart Research Programme and Lab in South Africa.

Dr Dev Niyogi is an associate professor with joint appointment in the Departments of Agronomy and Earth, Atmospheric, and Planetary Science at Perdue University.

He is also the State Climatologist for Indiana and Director of the Indiana State Climate Office. His research seeks to advance the understanding of vegetation and land surface processes in environmental, weather forecasting, and climate analyses, using a combination of dynamical models and surface, satellite remote sensing, and multiscale analysis products.

His research deals with the understanding and representation of the effects of vegetation – land surface processes in environmental processes at different scales. He is one of the three invited, nonfederal representatives to the community modeling effort of the Weather Research and Forecast (WRF) model working group on Land Surface Models, and to the Federal Geophysical Data Commission (FGDC) Spatial Climate Working Group.

He has authored or coauthored 25 successful proposals for external grants totaling over $3M. He vertically integrates undergraduate, graduate, and postdoctoral researchers in his research and is very interdisciplinary in developing collaborative projects.

Dr George Kallos is a professor at the University of Athens, School of Physics, Division of Environmental Physics and Meteorology. He leads the Atmospheric Modeling and Weather Forecasting Group (AM & WFG). He has a BSc from the University of Athens/School of Mathematics (1975). He obtained his MSc (1983) and PhD (1985) in Geophysical Sciences/ Atmospheric Sciences Division, Georgia Institute of Technology, School of Geophysical Sciences, USA. He has 110 publications in peer review scientific journals, more than 230 presentations and publications in conference proceedings publications, 10 contributions in books and more than 200 other publications in subjects related to atmospheric physics and chemistry, sea-state conditions, and renewable energy production. He has been invited 70 times to give talks in conferences, seminars, etc. His published work has received >2000 citations. He has participated in 80 projects. He has organized 12 conferences related to air pollution and dust transport in the Mediterranean. He has supervised 10 PhDs and over 100 MSc theses and participated in 20 PhD examinations in Greece and Europe. He is an associate editor for the journals: '*Environmental Fluid Mechanics*', '*Advances in Meteorology*', '*International Journal of Geosciences*', '*Atmospheric Pollution Research*', and '*Journal of Aerospace Operations*'. He was awarded the International Union of Air Pollution Prevention Association – IUAPPA award for his work on 'Long-range transport and air quality work in the Mediterranean region'. His current research activities are related to atmospheric, climatic, air pollution, and sea-state model development and forecasting. He focuses in fully coupled modeling systems. The latest model developments are related to nucleation processes in clouds, desert dust cycle and its direct and indirect effects. Research activities related to renewable energy resources (wind, ocean, solar) are focusing on high accuracy atmospheric model development, energy relationships and predictions, and protection from extremes.

Timothy Seastedt received his BA in biology from the University of Montana, an MS degree in biological sciences from the University of Alaska at Fairbanks, and a PhD degree from the University of Georgia. He was on the faculty at Kansas State University and is currently a professor of Ecology and Evolutionary Biology and fellow of INSTAAR at the University of Colorado, Boulder. Much of his research has been conducted as part of the Long-Term Ecological Research (LTER) programs at KSU and CU. His interests focus on terrestrial ecosystem ecology and the causes and consequences of biotic change. His recent activities have emphasized the ongoing changes found along the grassland to (melting) glacier gradient that exists in the Colorado Front Range.

Katharine Suding received her BA in biology from Williams College and a PhD degree from the University of Michigan. She was on the faculty at University of California Irvine and is currently a professor in Environmental Science, Policy and Management at the University of California Berkeley. Her background is in plant community and ecosystem ecology, with current interests in restoration, resilience, and environmental change.

Faisal Hossain received his PhD from the University of Connecticut in 2004. Prior to that, he had earned his MS and BS from the National University of Singapore and Indian Institute of Technology, Varanasi, respectively. He is currently an associate professor in the Department of Civil and Environmental Engineering where he received one of the highest awards of University – the Caplenor Research Award in 2012. His research interests comprise hydrologic remote sensing, uncertainty modeling of water cycle variables, human modification of extreme hydro-climatology, sustainable water resources engineering, space-borne transboundary water resources management, engineering education, and public outreach. He is also the recipient of awards such as NASA Earth System Science Fellowship (2002), Outstanding PhD Thesis Award (2005), NASA New Investigator Award (2008), American Society of Engineering Education (ASEE) Outstanding Research Award (2009), National Association of Environmental Professionals Education Excellence Award (2010), US Fulbright Faculty Award (2012), G.O.L.D. (Graduate Of the Last Decade) award from University of Connecticut (2012), and American Geophysical Union (AGU) Charles Falkenberg Award. He has published over 85 peer-reviewed journal articles, authored an undergraduate-level textbook, edited two book volumes, and contributed eight book chapters. His recent research on human modification of extreme events by artificial reservoirs has been featured by public media such as the BBC, National Geographic, New Scientist, Newsweek, Fox News, MSNBC, Wired.com, and German Public Radio. He served as an associate editor of *Journal of American Water Resources Association* from 2006–10. Currently, he serves as an associate editor for *Journal of Hydrometeorology* and a lead editor for the water volume of Elsevier Sciences five volume reference series on '*Climate Vulnerability: Understanding and Addressing Threats to Essential Resources*'.

PREFACE

We are pleased to introduce the five-volume set of books on bottom-up, resource-based vulnerability assessments of the societally and environmentally key resources of water, food, energy, human health and well-being, and ecosystem function. This inclusive bottom-up vulnerability concept requires the determination of the major threats to these resources from climate, but also from other social and environmental issues. After these threats are identified for each resource, the relative risk from natural- and human-caused climate change (estimated from global climate model (GCM) projections, as well as the historical, paleorecord, and worst case sequences of events) can be compared with other environmental and social risks in order to adopt the optimal mitigation and adaptation strategies.

The bottom-up, resource-based approach (referred to by O'Brien (2009) as ‘contextual vulnerability’) that is the focus of the volume is distinct from the Intergovernmental Panel on Climate Change (IPCC) top-down assessment of vulnerability based on the multidecadal GCM predictions (projections) which O'Brien defined as ‘outcome vulnerability’ (**Table 1** and **Figure 1**).

An excellent example of the contextual vulnerability is the paper by Romero-Lankao et al. (2012) who concluded in a study of the literature that urban vulnerability is dominated by epidemiological studies and top-down assessments, but that inherent urban vulnerability and urban resilience approaches (the contextual vulnerability) are what is required in order to illuminate a more complete set of drivers of urban vulnerability. They also showed that the large majority of papers on vulnerability use the outcome vulnerability approach. However, as discussed below, this top-down approach has major flaws.

First, there is the issue that the term ‘climate’ has two definitions. The broader view (and the one adopted by NRC (2005)) is that climate consists of the atmosphere, oceans, land, and cryosphere. This is the preferred usage. The second definition is that climate is the term used for the long-term (e.g., multidecadal) statistics of weather.

As reported in the NRC (2005) report and written in the Pielke et al. (2009) article with respect to human climate forcings.

> In addition to greenhouse gas emissions, other first-order human climate forcings are important to understanding the future behavior of Earth's climate. These forcings are spatially heterogeneous and include the effect of aerosols on clouds and associated precipitation [e.g., Rosenfeld et al. 2008], the influence of aerosol deposition (e.g., black carbon (soot) [Flanner et al. 2007] and reactive nitrogen [Galloway et al. 2004]), and the role of changes in land use/land cover [e.g., Takata et al. 2009]. Among their effects is their role in altering atmospheric and ocean circulation features away from what they would be in the natural climate system [NRC 2005]. As with CO_2, the lengths of time that they affect the climate are estimated to be on multidecadal timescales and longer.

and

> “…the natural causes of climate variations and changes are important, as are the human influences. The human climate forcings involve a diverse range of first-order climate forcings, including, but not limited to, the human input of carbon dioxide (CO2). Most, if not all, of these human influences on regional and global climate will continue to be of concern during the coming decades.”

Threats from climate involve any one or combination of climate variables as illustrated in **Figure 2**. There do not, of course, have to be changes in the statistics of these variables to constitute a risk. The term

Table 1 Contrast between a top-down versus bottom-up assessment of the vulnerability of resources to climate variability and change

Approach	*Comparative vulnerability*	*Contextual vulnerability*
Assumed dominant stress	Climate, recent greenhouse gas emissions to the atmosphere, ocean temperatures, aerosols, etc.	Multiple stresses: climate (historical climate variability, land use and water use, altered disturbance regimes, invasive species, contaminants/pollutants, habitat loss, etc.)
Usual timeframe of concern	Long-term, doubled CO_2 30–100 years in the future.	Short-term (0–30 years) and long-term research.
Usual scale of concern	Global, sometimes regional. Local scale needs downscaling techniques. However, there is little evidence to suggest that present models provide realistic, accurate, or precise climate scenarios at local or regional scales.	Local, regional, national, and global scales.
Major parameters of concern	Spatially averaged changes in mean temperatures and precipitation in fairly large grid cells with some regional scenarios for drought.	Potential extreme values in multiple parameters (temperature, precipitations, frost-free days) and additional focus on extreme events (floods, fires, droughts, etc.) measures of uncertainty.
Major limitations for developing coping strategies	Focus on single stress limits preparedness for other stresses. Results often show gradual ramping of climate change-limiting preparedness for extreme events. Results represent only a limited subset of all likely future outcomes – usually unidirectional trends. Results are accepted by many scientists, the media, and the public as actual 'predictions'. Lost in the translation of results is that all models of the distant future have unstated (presently unknowable) levels of certainty or probability.	Approach requires detailed data on multiple stresses and their interactions at local, regional, national, and global scales, and many areas lack adequate information. Emphasis on short-term issues may limit preparedness for abrupt "threshold" changes in climate sometime in the short or long term. Requires preparedness for a far greater variation of possible futures, including abrupt changes in any direction – this is probably more realistic, yet difficult.

Adapted from Kabat et al. 2004.

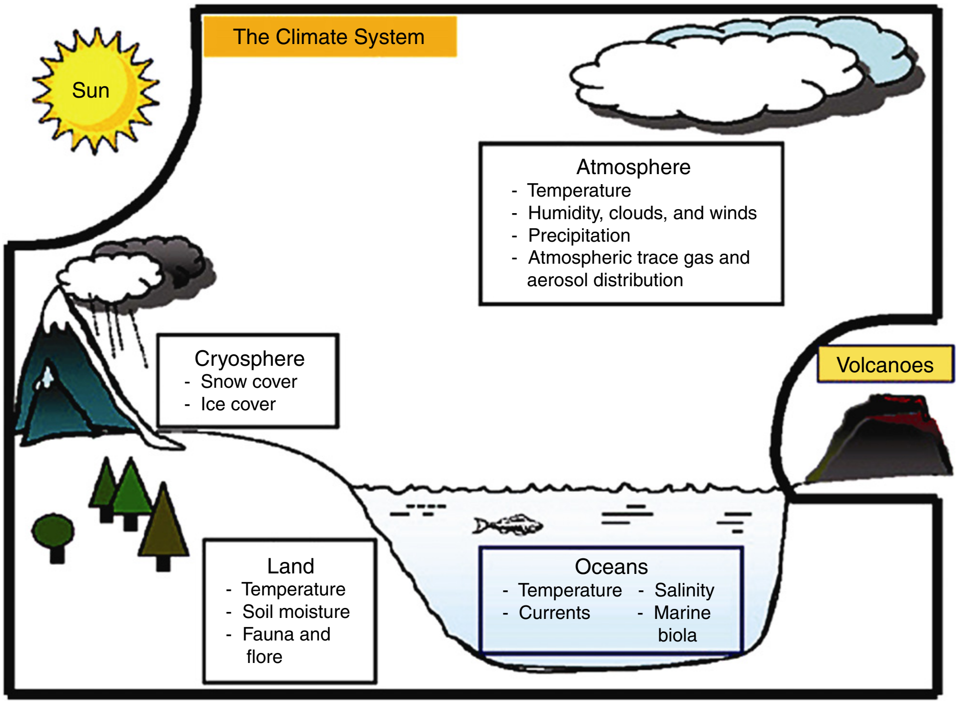
Figure 1 Framework depicting two interpretations of vulnerability to climate change: (a) outcome vulnerability and (b) contextual vulnerability. *From: Füssel (2009) and O'Brien et al. (2007).*

'climate change' should be used to describe any multidecadal or longer alteration in one or more physical, chemical, and/or biological components of the climate system, but as explained below, this terminology has morphed into multiple, diverse (and often mutually exclusive) definitions as used by the impacts communities.



The Climate System
Sun
Atmosphere
- Temperature
- Humidity, clouds, and winds
- Precipitation
- Atmospheric trace gas and aerosol distribution
Cryosphere
- Snow cover
- Ice cover
Volcanoes
Land
- Temperature
- Soil moisture
- Fauna and flore
Oceans
- Temperature
- Currents
- Salinity
- Marine biola

Figure 2 The climate system, consisting of the atmosphere, oceans, land, and cryosphere. Important state variables for each sphere of the climate system are listed in the boxes. For the purposes of this report, the Sun, volcanic emissions, and human-caused emissions of greenhouse gases and changes to the land surface are considered external to the climate system (NRC 2005).

First, climate is never static (Lovejoy and Schertzer 2012). As written in Rial et al. (2004)

> "The Earth's climate system is highly nonlinear: inputs and outputs are not proportional, change is often episodic and abrupt, rather than slow and gradual, and multiple equilibria are the norm."

The assumption of a stable climate system (e.g., the reason for the use of the terminology 'climate stabilization') in the absence of human intervention is a mischaracterization of the behavior of the real climate system. Humans are now adding to the complexity of forcings and feedbacks, but change has always been a part of the climate system. 'Climate change' is, and always has, been occurring. The added word 'change' is, therefore, redundant.

Moreover, there are additional misunderstandings. 'Global warming', which is an increase in the global annual average heat content measured in Joules, is often incorrectly equated to mean 'climate change'. Global warming, however, is just a subset of "climate change."

The term 'climate change', is also being erroneously used to mean only 'anthropogenic caused changes in climate' from nearly 'static' climatic conditions. Frequently, just the human input of greenhouse gases is assumed to be the reason for 'climate change'. For example, NRC (2010) (Climate Stabilization Targets: Emissions, Concentrations, and Impacts Over Decades to Millennia (2010)) states

> "This new report from the National Research Council concludes that emissions of carbon dioxide from the burning of fossil fuels have ushered in a new epoch where human activities will largely determine the evolution of Earth's climate."

Thus, the recommendations to the authors of the volume (not always accepted) were to replace terminology, such as climate change, climate stabilization, and climate disruption, with accurate terminology. When changes in climatic conditions are discussed, it was requested that the actual climate variables (such as temperature, precipitation, length of growing season) that are being altered, be specified. Phrases such as 'changes in regional and global climate statistics' could also be used.

There is a very fundamental reason to limit the use of 'climate change' by the impacts community. Key societal and environmental resources, such as water, food, energy, ecosystem function, and human health respond to climate, not just to an incremental change in the climatic conditions. As noted earlier, the assumption of a stable climate system, in the absence of human intervention, is a mischaracterization of the behavior of the real climate system.

However, some authors retained the use of the terminology 'climate change'. It was acquiesced as long as there was a significant contribution in their chapter to a broad-based assessment of risk to the key resource they were discussing.

Another misused term is 'global change', when really what is almost always meant is a local and/or regional change in the environmental conditions, including from climate. The accurate terminology should be 'environmental change'. The term 'environmental change' is, therefore, preferred rather than 'global change', as the latter terminology is very much a top-down viewpoint. Almost all impacts on key resources are on the local and regional scale.

We also requested the authors start with the risks and factor in the climate threats after thresholds, etc. were first obtained. This was not done in some chapters, but this information can still be extracted from the text. Obtaining the spectrum of risks first is the more inclusive way to assess threats to key resources, and thus, in the view, to prepare the optimal mitigation and adaptation strategies.

For the climate component of risk, the outcome vulnerability (the top-down) approach relies on skillful weather predictions and analyzes with a regional and a local focus. For weather prediction on time periods of days to a week or two, excellent skillful predictions are available for use in outcome vulnerability assessments. On seasonal timescales, there is also some limited predictive skill to apply to outcome vulnerability assessments, particularly for such well-defined weather events such as an El Niño or La Niña (Castro et al. 2007). However, for decadal and multidecadal predictions little, if any, predictive skill has been shown in hindcast climate model predictions of changes in regional weather statistics beyond what is available to the impacts community via the historical, recent paleorecord and a worst case sequence of weather events.

To illustrate the lack of skill, the conclusions from several papers have been summarized. Fyfe et al. (2011) concluded that

> "….for longer term decadal hindcasts a linear trend correction may be required if the model does not reproduce long-term trends. For this reason, we correct for systematic long-term trend biases."

Xu and Yang (2012) find that without tuning from real world observations, the model predictions are in significant error. For example, they found that

> …the traditional dynamic downscaling (TDD) [i.e. without tuning) overestimates precipitation by 0.5-1.5 mm d-1…..The 2-year return level of summer daily maximum temperature simulated by the TDD is underestimated by 2-6°C over the central United States-Canada region."

The paper van Oldenborgh et al. (2012) report just limited predictive skill in two regions of the oceans on the decadal time period, but no regional skill elsewhere, when they conclude that:

> "A 4-model 12-member ensemble of 10-yr hindcasts has been analysed for skill in SST, 2m temperature and precipitation. The main source of skill in temperature is the trend, which is primarily forced by greenhouse gases and aerosols. This trend contributes almost everywhere to the skill. Variation in the global mean temperature around the trend does not have any skill beyond the first year. However, regionally there appears to be skill beyond the trend in the two areas of well-known low-frequency variability: SST in parts of the North Atlantic and Pacific Oceans is predicted better than persistence. A comparison with the CMIP3 ensemble shows that the skill in the northern North Atlantic and eastern Pacific is most likely due to the initialisation, whereas the skill in the subtropical North Atlantic and western North Pacific are probably due to the forcing."

Anagnostopoulos et al. (2010) report that

> "…. local projections do not correlate well with observed measurements. Furthermore, we found that the correlation at a large spatial scale, i.e. the contiguous USA, is worse than [even] at the local scale."

Stephens et al. (2010) wrote

> "models produce precipitation approximately twice as often as that observed and make rainfall far too lightly…..The differences in the character of model precipitation are systemic and have a number of important implications for modeling the coupled Earth system …….little skill in precipitation [is] calculated at individual grid points, and thus applications involving downscaling of grid point precipitation to yet even finer-scale resolution has little foundation and relevance to the real Earth system."

van Haren et al. (2012) concluded from their study with respect to climate model predictions of precipitation that

> "An investigation of precipitation trends in two multi-model ensembles including both global and regional climate models shows that these models fail to reproduce the observed trends….. A quantitative understanding of the causes of these trends is needed so that climate model based projections of future climate can be corrected for these precipitation trend biases…. To conclude, modeled atmospheric circulation and SST trends over the past century are significantly different from the observed ones."

Sun et al. (2012) found that

> "…in global climate models, [t]he radiation sampling error due to infrequent radiation calculations is investigated …….. It is found that…. errors are very large, exceeding 800 W m^{-2} at many non-radiation time steps due to ignoring the effects of clouds…."

There is an important summary of the limitations in multidecadal regional climate predictions in Kundzewicz and Stakhiv (2010) who succinctly conclude that

> "Simply put, the current suite of climate models were not developed to provide the level of accuracy required for adaptation-type analysis."

Since the top-down outcome vulnerability approach depends on skillful decadal and longer regional and local climate predictions, yet they have shown little if any skill, another approach is needed.

For this reason, the volume set of five books presents an alternate approach – the bottom-up, resource-based outcome (contextual) vulnerability perspective. The goal of the set was to focus on the climate component of stress but also consider, in-depth, other environmental and social threats.

The text of the articles is written at a level that allows undergraduate students to understand the material, while providing active researchers with a ready reference resource for information in the respective field.

The questions requested to the authors address with respect to a specific resource were:

1. Why is this resource important? How is it used? To what stakeholders is it valuable?
2. What are the key environmental and social variables that influence this resource?
3. What is the sensitivity of this resource to changes in each of these key variables? This includes, but is not limited to, the sensitivity of the resource to climate variations and change on short (e.g., days), medium (e.g., seasons), and long (e.g., multidecadal) timescales.
4. What changes (thresholds) in these key variables would have to occur to result in a negative (or positive) response to this resource?
5. What are the best estimates of the probabilities for these changes to occur? What tools are available to quantify the effect of these changes? Can these estimates be skillfully predicted?
6. What actions (adaptation/mitigation) can be undertaken in order to minimize or eliminate the negative consequences of these changes (or to optimize a positive response)?
7. What are specific recommendations for policymakers and other stakeholders?

There are also overview chapters that discuss the science of the resource.

Several authors insisted on focusing on the use of the outcome vulnerability (top-down) approach based on the multidecadal GCM projections (statistically or dynamically downscaled) as the starting point of their chapters. The chapters were accepted, despite this shortcoming, because when they finally discussed adaptation in their text, they did present the broader-based bottom-up focus that is the centerpiece of the volume. Readers,

however, need to be aware that the top-down, GCM scenarios are only a subset, at best, of what is plausible in the coming decades. Multidecadal predictions of changes in regional and local climate statistics have not shown skill when run in a hindcast mode for the past several decades.

In summary, the goal of the five-volume set of books is to document the value of a bottom-up, resource-based assessment of risk to key resources, as illustrated schematically in Figure 3a–e. Most, but not all, authors accepted this framework. This can be assessed without having any predictability on

multidecadal time periods. It is an alternative (and more inclusive) perspective than the IPCC top-down outcome vulnerability approach which starts with the GCMs as the overarching framework. In the bottom-up approach, the scenarios from the GCM predictions should only enter after the specific threats to the resources are determined and even then, they provide, at best, a limited set of insights into what is possible.

Preface - Vulnerability of Ecosystems to Climate

TR Seastedt, University of Colorado, Boulder, CO, USA
KN Suding, University of California, Berkeley, CA, USA

© 2013 Elsevier Inc. All rights reserved.

Ecologists tend to focus on local and regional phenomena. Our ability to experiment on complex ecological systems usually means that we work at small spatial scales. Such an approach has resulted in our contention that local ecological systems have very large effects on the outcome of experiments involving environmental change drivers across the Earth such as those described below. The last few years have seen an explosion of studies documenting how human influences on the climate system will affect both natural and human-dominated ecosystems. Thus, when Roger Pielke Sr. asked us to become involved in a 'bottom-up approach' to dealing with the vulnerability of ecosystems to climate, we looked at this assignment with interest as a learning opportunity.

Environmental change factors are common and numerous, and many of these might be viewed as orthogonal or independent of changes in climate. Human-driven land use change, fragmentation, wildfires, increases in atmospheric nitrogen content, or increases in atmospheric pollutants, and so on have been ongoing for millennia, but these factors have intensified during the explosion of the human population over the last decades. As stated so succinctly by authors in this volume, changes associated with human population growth and resource use are first-order factors driving environmental changes, and these changes will be ongoing and in many cases intensifying during the coming decades.

A bottom-up perspective can mean several things: appreciating multiple climate forcings, appreciating that social and ecological interactions can influence response to these forcings, and appreciating that these forcings depend on other environmental change factors. Different authors emphasize different aspects of this bottom-up approach depending on the topic and expertise, but all bring home the point that we are dealing with complex systems in which vulnerability and sustainability require a broad and multifaceted approach. The current 'state of the environment' is generated by interaction effects and feedbacks, and rarely is the environmental status controlled by a single variable such as warming of the planet. Unfortunately, many people translate complexity and the inability to identify single factors as causal agents as 'uncertainty.' There is plenty of uncertainty out there; however, we are quite certain about the importance of the interactions among environmental change factors and have substantial knowledge of many of their combined effects and impacts. In order for ecosystem stewardship to be successful, we must embrace this complexity and not let uncertainty be an excuse for inaction.

What we are not certain about, given the complexity and nonlinearity of the interactions, are future conditions. The future will be created by decisions and actions yet to be determined as well as from incompletely understood behavior of the natural system. The future, when viewed at local, regional, and global scales, is somewhere between rosy and apocalyptic. Stakeholders don't get to choose the outcome, but their current decisions about abiotic and biotic resources contribute to this outcome. Although we have no crystal ball, the logic of pursuing 'win–win' decisions now that will contribute to the sustainability of urban to natural ecosystems is compelling and can move the outcome in ways that are beneficial to society.

Our goals are similar to companion volumes focusing on water, human health, agriculture, and energy. In the context of interactions and complexity in the current era of environmental change, we asked the authors to address:

- *What are the key issues or threats facing ecosystem processes and ecosystem services today?*
- *How do we use the understanding of these issues to increase resilience and sustainability in the near future?*

Because the 'near future' is a key focus, it avoids assessments based purely on the commonly studied 50 or 100 year emission-driven scenarios of future climate. The more pressing question for local stakeholders is:

- *What do we need to do right now so that we can do an even better job of ecosystem stewardship in the future?*

We are pleased to be able to draw on the breadth of knowledge about ecosystems and environmental change by bringing together chapters composed by a wide range of eminent scientists investigating aspects of the local drivers, responses, and feedbacks critical to understanding the complexity and nonlinearity of systems in the future. Biogeochemists, ecologists, anthropologist, and economists have weighed in on the topic. The chapters reflect this interdisciplinary and broad approach to sustainability and vulnerability: some highly quantitative, others more qualitative, some very place-based, others seeking more general phenomena. This diversity in approaches reflects the importance of multiple pathways toward knowledge generation; indeed, as Terry Chapin points out in the introductory chapter, sustainability and well-being are value-based normative concepts seen through many frames by a diverse set of stakeholders. Because their assessment is as much a political as a scientific process across a large diverse set of stakeholders, we need this diversity in order to effectively link vulnerability analyses to decision making.

We have organized this book to provide three types of perspectives in considering vulnerability: from threats to ecosystems and their services (Section 1, Chapters 2–7), from focal ecosystem processes and services (Section 2, Chapters 8–14), and from place-based or specific system assessments (Section 3, Chapters 15–25). The volume ends with a focus on planning, mitigation, and adaptation strategies. We are delighted by the many linkages among the different perspectives, in part reflecting that no one approach will be a silver bullet to address these issues.

Where do we go from here? The phrase, 'think globally, act locally,' attributed to Patrick Geddes in 1915 continues to resonate a century later. However, the point of this volume and others in this series is that by acting locally, one not only can change the world, but also can mitigate some of what the world is going to throw at us. Moreover, as each locality will get thrown a different set of challenges, we cannot expect one-size-fits all solutions. Ecosystem stewardship will need to reflect this place-based context.

4.01.1 Introduction

The world is undergoing unprecedented changes in many of the factors that determine both its fundamental properties and their influence on society. Throughout human history, people have interacted with and shaped ecosystems for social and economic development (Turner et al. 1990; Redman 1999; Jackson 2001; Diamond 2005). During the last 50 years, however, human activities have changed ecosystems more rapidly and extensively than at any comparable period of human history (Steffen et al. 2004; Foley et al. 2005; MEA 2005). Regions of the Earth's climate for example, are now warmer than at any time in the last 500 (and probably the last 1300) years (IPCC 2007), in part because of atmospheric accumulation of carbon dioxide (CO_2) released by the burning of fossil fuels (**Figure 1**). Agricultural development largely accounts for the accumulation of other trace gases that contribute to further changes in the composition of the Earth's atmosphere (Foley et al. 2011). As the human population increases, an increased demand for food and natural resources has led to an expansion of agriculture, forestry, and other human activities, causing large-scale land-cover change and loss of habitats and biological diversity. Approximately half the world's population now lives in cities and depends on connections with rural areas worldwide for food, water, and waste processing. In addition, increased human mobility is spreading plants, animals, diseases, industrial products, and cultural perspectives more rapidly than ever before. This increase in global mobility, coupled with increased connectivity through global markets and new forms of communication, links the world's economies and cultures, so decisions in one place often have international consequences.

This globalization of economy, culture, and ecology is important, because it modifies the life-support system of the planet (Odum 1989), that is, the capacity of the planet to meet the needs of all organisms, including people. The dramatic increase in the extinction rate of species (100–1000-fold in the last two centuries) indicates that global changes have been catastrophic for many species, although some species, especially invasive species and some disease organisms, have benefited and expanded their ranges (Mace et al. 2005).

The unique feature of the changes described above is that they are directional. In other words, they show a persistent trend over time (**Figure 1**). Many of these trends have become more pronounced since the mid-twentieth century and will probably continue or accelerate in the coming decades, even if society takes concerted actions to reduce some rates of change. This situation creates a dilemma in planning for the future, because we cannot assume that the future world will behave as we have in the past or that our past experience provides an adequate basis to plan for the future. We must adopt a more flexible approach to managing ecosystems – management to sustain the functional properties of ecosystems that are important to society, under conditions where the system itself is constantly changing.

Changes in the Earth System are highly interconnected. None of the changes mentioned above are purely physical, ecological, or social. Therefore, understanding current and future change requires a broad interdisciplinary framework that draws on the concepts and approaches of many natural and social sciences. We must understand the world, region, or community as a social-ecological system in which people depend on resources and services provided by ecosystems. Ecosystem dynamics are influenced, to varying degrees, by human activities (Berks et al. 2003; Turner et al. 2003; Steffen et al. 2004). Although the relative importance of social and ecological processes may vary from forests to farms to cities, the functioning of each of these systems, and of the larger

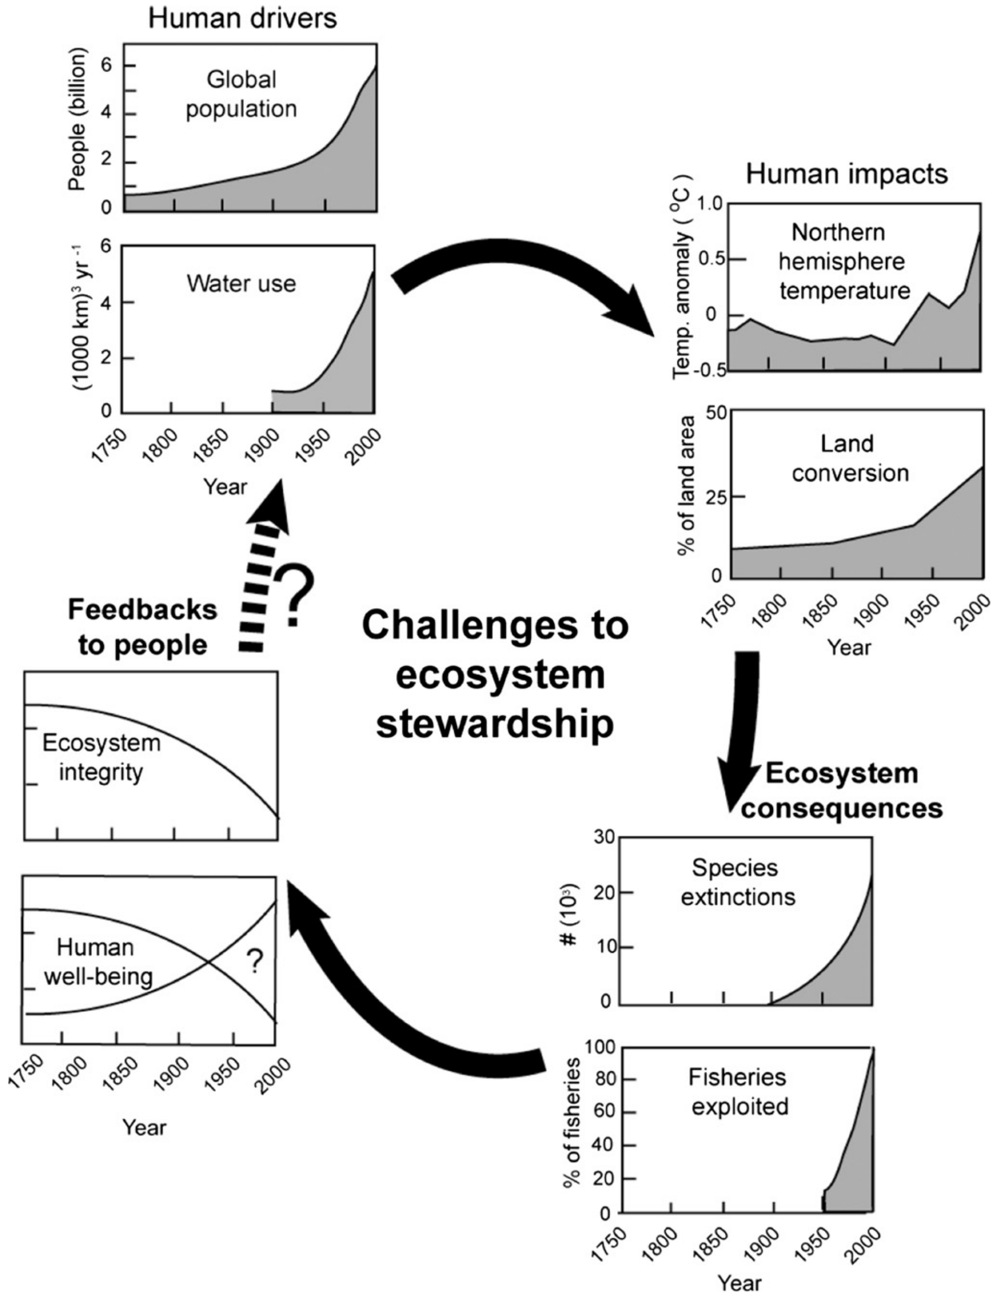

Figure 1 Challenges to ecosystem management and stewardship. Changes in human population and resource consumption alter climate and land cover, which have important ecosystem consequences such as species extinctions and over-exploitation of fisheries. These changes reduce ecosystem integrity and have regionally variable effects on well-being, which feed back to further changes in human drivers. Redrawn from Chapin III, F. S., G. P. Kofinas, and C. Folke, Eds., 2009: *Principles of Ecosystem Stewardship: Resilience-Based Natural Resource Management in a Changing World*. Springer, New York with panels from Steffen, W. L., A. Sanderson, P. D. Tyson, J. Jäger, P. A. Matson, et al., 2004: *Global Change and the Earth System: A Planet under Pressure*. Springer-Verlag, New York.

regional system in which they are embedded, is strongly influenced by physical, ecological, economic, and cultural factors. Therefore, they are best viewed, not as ecological or social systems, but as social–ecological systems that reflect the interactions of physical, ecological, and social processes (Figure 2).

In studying the response of social–ecological systems to directional change, we pay particular attention to the processes that link ecological and social components (Figure 2). The environment affects people through environmental events, the direct effects of physical processes such as floods and droughts, and ecosystem services, and the benefits that people derive

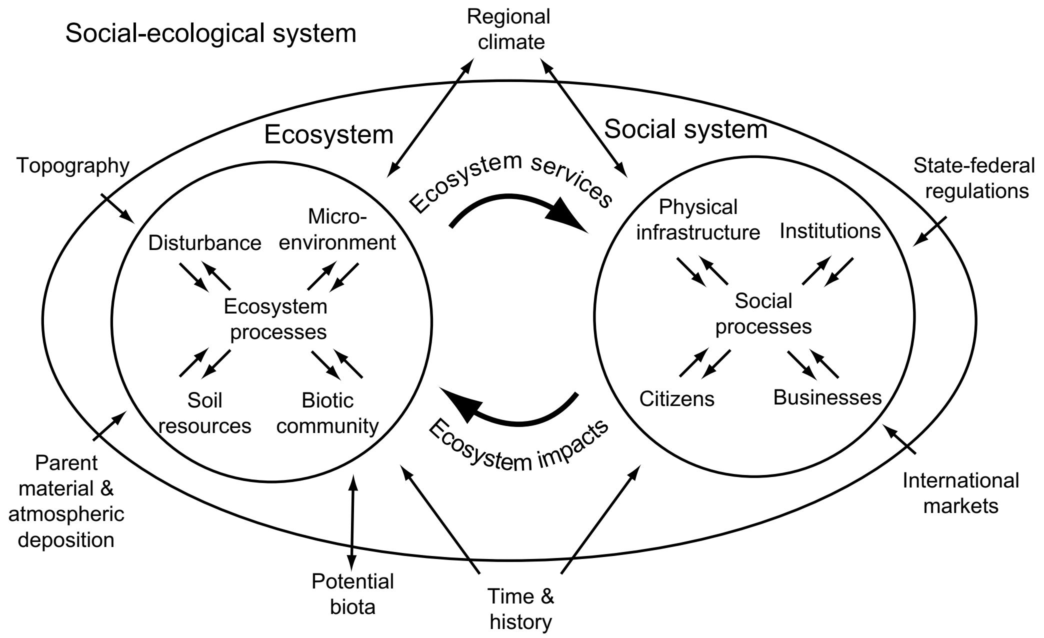

Figure 2 Controls over the functioning of social–ecological systems. Human impacts on ecosystems are mediated by a variety of social processes, and society benefits from the services provided by ecosystems. Modified from Whiteman, G., B. C. Forbes, J. Niemelä, and F. S. Chapin, III, 2004: Bringing feedback and resilience of high-latitude ecosystems into the corporate boardroom. *Ambio*, **33**, 371–376.

from ecosystems. Society in turn affects ecosystems through the impacts of human activities.

4.01.2 Vulnerability, Resilience, Sustainability, and Stewardship of Ecosystem Services

Given the rapid global changes that are occurring, it is important to consider rigorously the vulnerability, resilience, sustainability and stewardship associated with changes in ecosystems. We introduce each of these concepts in this section.

4.01.2.1 Vulnerability

Vulnerability is the degree to which a system is likely to experience harm due to exposure to a specified hazard or stress (Turner et al. 2003; Adger 2006). Vulnerability theory is rooted in socio-economic studies of impacts of events (e.g., floods or wars), or stresses (e.g., chronic food insecurity) on social systems, but has been broadened to address responses of ecosystems and entire social–ecological systems. Vulnerability analysis deliberately addresses human values, such as equity and well-being. Vulnerability to a given stress can be reduced by (1) reducing exposure to the stress (mitigation); (2) reducing sensitivity of the system to stress by sustaining ecological integrity and the components of human well-being; and/or (3) increasing adaptive capacity and resilience (see below) to cope with stress (Turner et al. 2003).

Exposure to a stress can be reduced by minimizing its intensity, frequency, duration, or extent. Prevention of pollution or banning of toxic pesticides, for example, reduces the vulnerability of people who would otherwise be exposed to these hazards. Mitigation (reduced exposure) is especially challenging when the stress is the cumulative effect of processes occurring at scales that are larger than the system being managed. Anthropogenic contributions to climate change through the burning of fossil fuels, for example, is globally dispersed, so it cannot be reversed by actions taken solely by those regions that experience the greatest impacts of climatic change (McCarthy et al. 2005). Other globally or regionally dispersed stresses include inadequate supplies of clean water and uncertain availability of nutritious food (Steffen et al. 2004; Kasperson et al. 2005).

Sensitivity to a stress can be reduced in at least three ways: (1) sustaining the slowly changing ecological variables that determine natural capital (i.e., the natural resources that support the functioning of ecosystems); (2) maintaining key components of well-being; and (3) paying particular attention to the needs of the disadvantaged segments of society, who are generally most vulnerable. The poor or disadvantaged, for example, are especially vulnerable to food shortages or economic downturns, and people living in floodplains or the wildland–urban interface are especially vulnerable to flooding or wildfire, respectively. An understanding of the causes of differential vulnerability can lead to strategies for targeted interventions to reduce overall vulnerability of the social–ecological system.

4.01.2.2 Resilience

Resilience is the capacity of a social–ecological system to absorb a spectrum of shocks or perturbations, and to sustain and develop its fundamental function, structure, identity, and feedbacks through either recovery or reorganization in a new context (Holling 1973; Gunderson and Holling 2002; Walker et al. 2004; Folke 2006). In a sense, it is the flexibility of the system to adjust to shocks and surprises. Resilience depends on

(1) the capacity of individual species or components of the system to adapt; (2) biophysical and social legacies that contribute to diversity and provide proven pathways for rebuilding; (3) the capacity of people to plan for the long term within the context of uncertainty and change; (4) a balance between stabilizing feedbacks that buffer the system against stresses, disturbance, and innovation that creates opportunities for change; and (5) the capacity to adjust governance structures to meet changing needs (Holling and Gunderson 2002; Folke et al. 2003; Walker et al. 2006). Loss of resilience pushes a system closer to its limits. When resilience has been eroded, a disturbance like a disease, storm, or market fluctuation, that previously shook and revitalized the resilient system, might now push the fragile system over a threshold into an alternative state with a new trajectory of change. Such system changes radically alter the flow of ecosystem services, associated livelihoods, and well-being of people and societies.

Sources of diversity, which is essential for adaptation, are critical to resilience. Fostering small-scale variability and change logically contributes to resilience, because it maintains within the system those components that are well adapted to each phase of the cycles of ecosystem disturbance and recovery. This reduces the likelihood that the inevitable disturbances will have catastrophic effects. Conversely, preventing small-scale disturbances such as insect outbreaks or fires tends to eliminate disturbance-adapted components, thereby reducing the capacity of the system to cope with disturbance.

4.01.2.3 Sustainability

Sustaining the desirable features of our current world for future generations is an important societal goal. The challenge of doing so in the face of persistent directional trends in underlying controls has led to an emerging science of sustainability (Clark and Dickson 2003). In this book we use the United Nations Environment Programme's definition of sustainability: the use of the environment and resources to meet the needs of the present without compromising the ability of future generations to meet their own needs (WCED 1987). According to this definition, sustainability requires that people be able to meet their own needs, that is, to sustain human well-being now and in the future (Dasgupta 2001). Since sustainability and well-being are value-based concepts, there are often conflicting visions about what should be sustained and how sustainability should be achieved. Thus, the assessment of sustainability is as much a political as a scientific process, and requires careful attention to whose visions of sustainability are being addressed (Shindler and Cramer 1999). Nonetheless, any vision of sustainability ultimately depends on the life-support capacity of the environment and the generation of ecosystem services.

4.01.2.4 Stewardship

Given the challenges of sustainable use of ecosystems during times of rapid change, a hands-off approach to managing ecosystems is no longer sufficient to sustain ecosystem services and the needs of society. Ecosystem stewardship is the shaping of trajectories of social–ecological change to sustain ecosystem resilience and human well-being. Stewardship is challenging because we are often uncertain about future trajectories of change. However, uncertainty has always characterized social–ecological systems and should therefore not be an excuse for inaction. Stewardship inevitably entails tradeoffs, particularly between efficiency and flexibility and between immediate and long-term benefits (Kareiva et al. 2007; Chapin et al. 2009).

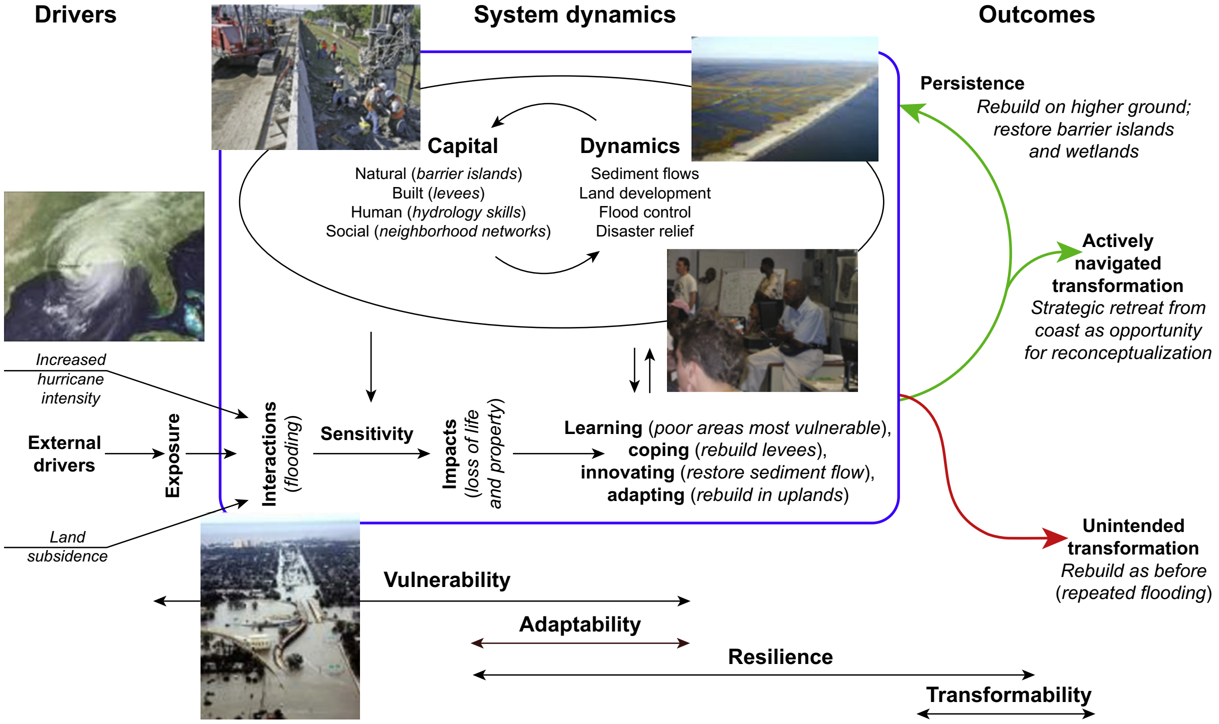
Ecosystem stewardship integrates three broadly overlapping sustainability approaches (Figure 3): reducing vulnerability to expected changes; fostering resilience to sustain desirable conditions in the face of perturbations and uncertainty; and transforming from undesirable trajectories when opportunities emerge. The need is to identify pragmatic strategies that increase the likelihood of socially beneficial outcomes and reduce the risk of bad outcomes. This approach is explicitly focused on human norms, values, and well-being and must therefore continually be debated and reassessed by stakeholders.

4.01.2.5 Ecosystem Services

Ecosystem services are the benefits that society receives from ecosystems. They provide a pragmatic framework for managing ecological sustainability. Ecosystems provide well-recognized provisioning services (goods), including water, timber, forage, fuels, medicines, and precursors to industrial products that are harvested from ecosystems. Ecosystems also provide regulatory services such as recycling of water and chemicals, mitigation of floods, pollination of crops, and cleansing of the atmosphere, as well as cultural services that meet recreational, aesthetic, and spiritual needs (Figure 4; Daily 1997; MEA 2005). All of these services depend on ecosystem processes that are sometimes known as supporting services. These processes include biogeochemical cycles, diversity maintenance, and disturbance cycles. Unless these underlying ecosystem properties are maintained, other services that are more directly recognized and valued by society cannot be sustained.

The overuse or misuse of resources can alter the functioning of ecosystems and the services they provide. Land-use change, for example, can degrade the capacity of watersheds to purify water, leading to large water treatment costs to cities (Grove 2009). Degradation and loss of wetlands can expose communities to increased damage from floods and storm surges (Kates et al. 2006). Decimation of populations of insect pollinators has reduced yields of many crops (Ricketts et al. 2004). Human caused introductions and invasions of non-native species such as killer bees, fire ants, and zebra mussels, cause enormous damage to living resources and threaten human health (Patz et al. 2005; Díaz et al. 2006). Human activities also indirectly affect ecosystem goods and services through changes in the atmosphere, hydrologic systems, and climate.

Management decisions often involve choices that reflect tradeoffs among ecosystem services. Forest harvest, for example, yields forest products at the expense of recreational opportunities provided by the uncut forest. Policies that enhance recreational values to snow machine users may diminish their value to cross-country skiers. Deforestation of tropical forests may provide local users with both forest products and land to support agriculture, but degrade soils in ways that diminish the livelihood opportunities for future generations. An important step in ecosystem management is to



Drivers
System dynamics
Outcomes
Capital
Natural (barrier islands)
Built (levees)
Human (hydrology skills)
Social (neighborhood networks)
Dynamics
Sediment flows
Land development
Flood control
Disaster relief
Persistence
Rebuild on higher ground; restore barrier islands and wetlands
Actively navigated transformation
Strategic retreat from coast as opportunity for reconceptualization
Increased hurricane intensity
External drivers
Exposure
Interactions (flooding)
Sensitivity
Impacts (loss of life and property)
Learning (poor areas most vulnerable),
coping (rebuild levees),
innovating (restore sediment flow),
adapting (rebuild in uplands)
Land subsidence
Unintended transformation
Rebuild as before (repeated flooding)
Vulnerability
Adaptability
Resilience
Transformability

Figure 3 Application of the ecosystem stewardship framework to the impact and response of New Orleans to Hurricane Katrina. A suite of external stresses (land subsidence from wetland drainage and increased hurricane intensity associated with warming) interact to create impacts (loss of life and property). Social learning (learning, coping, innovating, and adapting) in response to these impacts has the potential to alter social–ecological interactions and various forms of capital of the system (New Orleans, the blue box), which in turn influence sensitivity to future events. Social learning also governs the relative likelihood of three potential outcomes: persistence of the existing system through resilience; actively navigated transformation to a new, potentially more beneficial trajectory through transformation; or unintended degradation to a new state due to vulnerability and failure to adapt or transform. Reprinted from Chapin, F. S., III, S. R. Carpenter, G. P. Kofinas, C. Folke, N. Abel, et al., 2010: Ecosystem stewardship: sustainability strategies for a rapidly changing planet. *Trend. Ecol. Evol.*, **25**, 241–249.

assess potential impacts of decisions on multiple ecosystem services. This is challenging, given the huge number of services provided by ecosystems and uncertainties in their responses to a particular action. It is often pragmatic to focus particularly on a few critical ecosystem services, those services that are most vulnerable to change, have fewest options for technological or ecological substitution, and are most valued by society (A. Kinzig, 2012, pers. comm.).

4.01.3 Supporting Services: Sustaining Ecosystem Functioning

Supporting services are the fundamental ecological processes that control the structure and functioning of ecosystems. Managers and the public often overlook these services because they are not the products directly valued by society. Moreover, they are frequently controlled by slow variables (i.e., variables that change relatively slowly) and are therefore taken for granted by agencies tasked with managing particular ecosystem goods such as trees or fish. However, because of the fundamental dependence of all ecosystem services on supporting services, integrity of these services generally sustains many services that are valued more directly by society. This section focuses on the slow variables that most frequently control ecosystem processes, and therefore, a broad suite of ecosystem services.

4.01.3.1 Maintenance of Soil Resources

Soils and sediments are key slow variables that regulate ecosystem processes by providing resources required by organisms. The controls over the formation, degradation, and resource-supplying potential of soils and sediments are therefore central to sustaining the natural capital on which society depends (Birkeland 1999; Chapin et al. 2011). The quantity of soil in an ecosystem depends largely on the balance between inputs from weathering (the breakdown of rocks to form soil), or deposition and losses from erosion. In addition, organisms, especially plants, add organic matter to soils through death of tissues and individuals, which is offset by losses through decomposition. If an ecosystem were at a steady state (i.e., when inputs approximately equal outputs), then the quantity of soil would remain relatively constant, providing a stable capacity to supply vegetation with water and nutrients. Natural imbalances between inputs and outputs lead to deeper soils in floodplains and at the base of hills than on hilltops. When averaged over large regions, however, changes in soil capital due to imbalances between inputs and outputs usually occur slowly (approximately 0.1–10 mm per century) (Selby 1993). In general, the presence of a plant canopy and litter layer (the layer of dead leaves on the soil surface) reduces erosion. Human activities that reduce vegetation cover can increase erosion rates by several orders of magnitude, just as occurs naturally when glaciers,

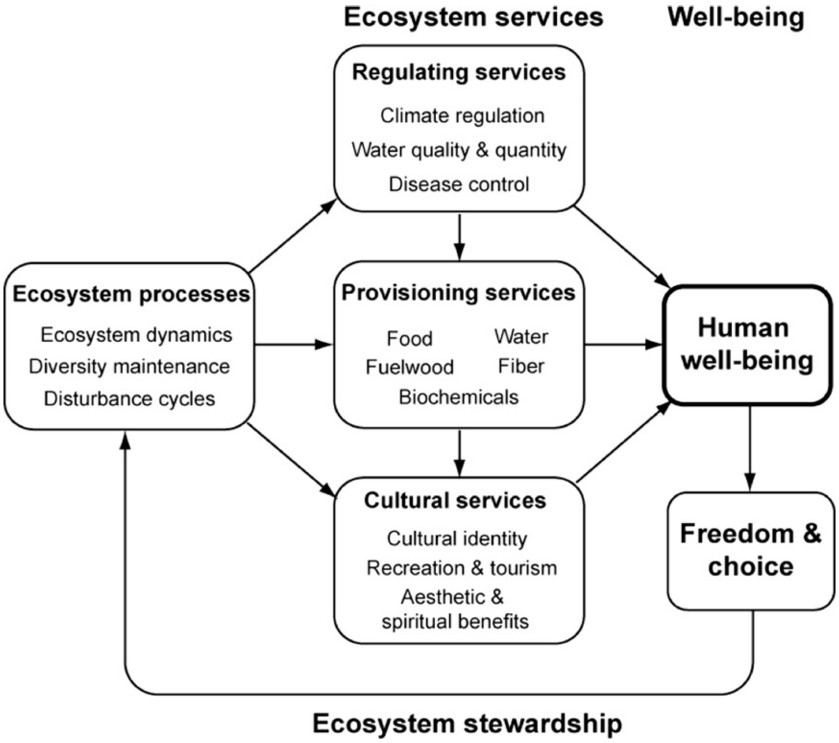


Figure 4 Linkages among ecosystem processes, ecosystem services, and the well-being of society, a framework developed by the Millennium Ecosystem Assessment (MEA 2005). Ecosystem processes are the foundation for ecosystem services that are directly used by society and which strongly influence human well-being. Human actions influence the life-support system of the planet through effects on environment (e.g., climate) and on ecosystems. Redrawn from Chapin, F. S., III, 2009: Managing ecosystems sustainably: the key role of resilience. F. S. Chapin, III, G. P. Kofinas, and C. Folke, Eds., *Principles of Ecosystem Stewardship: Resilience-Based Natural Resource Management in a Changing World*. Springer, New York, 29–53.

volcanoes, or landslides reduce vegetation cover. Under these circumstances, ecosystems can lose soils within a period of years to decades that may have required thousands of years to accumulate, causing an essentially permanent loss of the productive capacity of ecosystems. Similarly, human modification of river channels can alter sediment inputs.

4.01.3.2 Water Cycling

Water is the soil resource which is used in the largest quantities by plants and which most frequently limits the productivity of terrestrial ecosystems. Water enters ecosystems as precipitation. Two of the major pathways of water loss are transpiration, the 'green water' that supports terrestrial production, and runoff, which replenishes groundwater and aquatic ecosystems, the 'blue water' sources that are often tapped by people for domestic and industrial uses, irrigation, and hydropower. Consequently, there are inherent tradeoffs among the ecosystem services provided by water cycling, and some of the biggest challenges in water management result from these tradeoffs.

Climatic controls over precipitation place an ultimate constraint on quantities of water cycled through ecosystems. Within this constraint, the partitioning of water between transpiration and runoff depends on (1) the degree of compaction of the soil surface, which influences water infiltration into the soil, (2) soil water-holding capacity, which depends on the quantity of soil and its particle-size distribution, and (3) the capacity of vegetation to transpire water (Rockström et al. 1999).

Vegetation fosters infiltration and storage through several mechanisms. The plant canopy and litter reduce compaction by raindrops that otherwise tend to seal soil pores. In addition, roots and soil animals associated with vegetation create channels for water movement through the soil profile. By facilitating water infiltration (due to reduced compaction), water-holding capacity (due to production of soil organic matter), and reduced soil erosion (due to reduced overland flow), vegetation generates stabilizing feedbacks that sustain the productive potential of soils and reduce ecosystem vulnerability to drought (Bruijnzeel 2004; Uriarte et al. 2011). Human activities often disrupt these stabilizing feedbacks, thereby reducing resilience. For example, high densities of livestock or movement of heavy farm machinery at times (spring) or places (riparian corridors) where soils are wet can compact soils and reduce infiltration. Plowing reduces soil organic content substantially – often by 50% within a few years – thereby reducing soil water-holding capacity and the capacity of soils to support crop growth with natural rainfall (Matson et al. 1997). Alternative agricultural practices that conserve or rebuild soil organic content (e.g., no-till agriculture) or reduce compaction by livestock or equipment under wet conditions increase the capacity of soils to supply water to crops or other vegetation.

Transpiration is tightly linked to the capacity of plants to fix carbon and therefore to their productive potential. This explains why productive agricultural systems are such prodigious consumers of water and why streamflow increases after logging. At a more subtle level, any factor that increases the productive potential of vegetation (e.g., nutrient additions from fertilizers, introduction of exotic nitrogen-fixing species; atmospheric deposition of nitrogen; replacement of shrublands by forests) will increase transpiration (green water flows) and reduce water movement to groundwater and runoff (blue water flows). The tradeoffs between transpiration and runoff have implications for the role of ecosystems in regulating water flow (Jones et al. 2012).

4.01.3.3 Carbon and Nutrient Cycling

Within a climate zone, the availabilities of belowground resources (water and nutrients) are the main factors that constrain terrestrial carbon cycling and ecosystem productivity. The carbon, nutrient, and water cycles of terrestrial ecosystems are tightly linked. The major controls are (1) climate, which governs water inputs, rates of soil development, and cycling rates of carbon, nutrients, and water; (2) the water- and nutrient-holding capacity of soils, which depends on particle size and organic content; and (3) the productive capacity of vegetation (Hobbie 1996; Jobbagy and Jackson 2000; De Deyn et al. 2008) In addition, carbon and nutrient cycles are physically linked because carbon forms the skeleton of organic compounds that carry nitrogen and phosphorus among plants, animals, and soils.

4.01.3.4 Maintenance of Biological Diversity

The known effects of biodiversity on ecosystem functioning relate most strongly to traits that govern the effect of species on ecosystem processes and traits that govern the response of species to environmental variation. These known effects of biodiversity change (both loss of key species or invasion of species with large impacts) can be buffered by maintaining species that span the spectrum of effect diversity and response diversity present in the system (Elmqvist et al. 2003; Suding et al. 2008).

Keystone species are species that have disproportionately large effects on ecosystems, typically because they alter critical slow variables. Ecosystems are most likely to sustain their current properties if current keystone species (or their functional equivalents) are maintained, and new ones are not introduced. Species that influence the supply of growth-limiting resources generally have large effects on the functioning of ecosystems. *Morella faya*, for example, is a nitrogen-fixing tree introduced to nitrogen-poor ecosystems of Hawaii by the Polynesians. The resulting increases in nitrogen inputs, productivity, and canopy shading eliminated many plant species from the formerly diverse understory of this forest (Vitousek 2004). Highly mobile animals, such as salmon and sheep, act as keystone species governing nutrient supply by feeding in one place and dying or defecating somewhere else. Similarly, species that modify disturbance regime exert strong effects on ecosystem functioning through their effects on cycles of disturbance and recovery. The introduction of flammable grasses into a tropical forest, for example, can increase fire frequency and trigger a regime shift from forest to savanna (D'Antonio and Vitousek 1992). One of the main ways that animals affect ecosystem processes is through physical disturbance (Jones et al. 1994). Gophers, pigs, and ants, for example, disturb the soil, creating sites for seedling establishment and favoring early successional species. Elephants trample vegetation and remove portions of tree canopies, altering the competitive balance between trees and grasses in tropical savannas. Many keystone species exert their effect by modifying species interactions, for example by eating other species (e.g., forest pests) or competing or facilitating the growth of other species (Chapin et al. 2000). Conserving key functional types (i.e., a group of species that have similar effects on ecosystem processes) and preventing the invasion of novel functional types reduces the likelihood of large changes in ecosystem services.

Diversity in the environmental response of species can stabilize ecosystem processes. Many species in a community appear functionally similar, for example, algal species in a lake or canopy trees in a tropical forest (Scheffer and van Nes 2004). What are the ecosystem consequences of changes in diversity within a functional type (i.e., functional redundancy)? Differences in environmental responses among functionally similar species provide resilience by stabilizing rates of ecosystem processes (McNaughton 1977; Chapin and Shaver 1985). In mid-latitude grasslands, for example, cool season grasses are particularly productive under cool, moist conditions, and warm season grasses under hot, dry conditions. As environmental conditions fluctuate within and among years, different species attain a competitive advantage over other functionally similar species (i.e., other grasses), thus stabilizing rates of ecosystem processes of the entire community (Ives et al. 1999).

The functional redundancy associated with species diversity also provides insurance against more drastic changes in environment, such as those that may occur in the event of human mismanagement of ecosystems or change in climate. Radical changes in environment are unlikely to eliminate all species of a given functional type in a diverse ecosystem, allowing the surviving species to increase in abundance and maintain functions that might otherwise be seriously compromised. Overgrazing in Australian grasslands, for example, eliminated the dominant species of palatable grass, severely reducing the quantity of cattle that the ecosystem could support and exposing the soil to wind erosion. Fortunately, a previously rare grass species that was less palatable, survived the overgrazing and increased in abundance, when the dominant grass declined, thus maintaining grass cover and reducing potential degradation from erosion (Walker et al. 1999). These examples of diversity effects on resilience provide hints of the general importance of diversity in stabilizing ecosystem processes and associated ecosystem services and suggest that management that sustains diversity is critical to long-term sustainability.

4.01.3.5 Maintenance of Disturbance Regime

Disturbance shapes the long-term fluctuations in the structure and functioning of ecosystems, and therefore, their resilience and vulnerability to change. Disturbances are relatively discrete events that alter ecosystem structure and cause changes in resource availability or physical environment (Pickett and White 1985). Natural Disturbance is not something that 'happens' to ecosystems, but is an integral part of their functioning. Species are typically adapted to the disturbance regime (i.e., the characteristic severity, frequency, type, size, timing, and intensity of disturbance) that shaped their evolutionary histories. Grassland and boreal species, for example, resprout rapidly after fire or have reproductive strategies that enable them to colonize recent burns (Johnson 1992). In contrast, many tropical tree species produce a pool of young seedlings that grow slowly in the understory, 'waiting' until a hurricane or other event creates gaps in the canopy (Chazdon 2003). The tropical tree strategy is poorly adapted to fire, which would kill the understory seedlings, and the boreal trees are poorly adapted to wind, which would leave an organic seedbed unfavorable for post-

disturbance germination. Naturally occurring disturbances such as fires and hurricanes are therefore not 'bad'; they are normal properties of ecosystems and indeed are essential for the long-term resilience of species and community dynamics that characterize a particular ecosystem (Dale et al. 2001).

4.01.4 Ecosystem Stewardship and Sustainability: Where and When Will Ecosystem Services Be Most Vulnerable?

Seeking to skillfully forecast how an ecosystem could respond to future conditions is a daunting, but critical, task necessary to achieve sustainability. We do not expect systems to act uniformly in their vulnerability and resilience, and we do not expect that responses will always be gradual and uniform. A grand challenge will be to assess the predictability of both the nature (what systems, what attributes of these systems, what ecosystem services) and the timing (when rapid responses may occur) of local sensitivities to multiple interacting stressor and perturbations.

An ecosystem stewardship framework is one strategy to address this challenge and to best manage for vulnerability, foster resilience, and guide positive transformations. To achieve socially beneficial outcomes and reduce the risk of bad outcomes, the framework must go beyond the traditional vulnerability perturbation– stressor– consequence mindset. For instance, it is critical to take into account that systems, as well as particular components within a system, are rarely equally vulnerable or equally resilient. Stochastic and nonlinear elements operating on and within a coupled system can give rise to unexpected or surprise outcomes (Holling and Gunderson 2002; Folke 2006; Peters et al. 2004). Determining cause and effect links that affect vulnerability at the local and regional scales will be essential to developing assessment frameworks and institutional structures that pragmatically link vulnerability analyses to decision making (Chapin et al. 2011). This approach will need to be explicitly focused on human norms, values, and well-being and m\ust therefore continually be debated and reassessed by stakeholders.

Glossary

Ecosystem services Goods with direct market values, and services that maintain the production of goods and biodiversity (sensu 1997).

Eutrophication The enrichment of surface waters with plant nutrients (http://www.org/docrep/w2598e/w2598e06.htmfao).

Globalization The process by which businesses or other organizations develop international influence or start operating on an international scale (*Oxford Dictionary*).

Human footprint (or Ecological footprint) The area of productive land and water ecosystems required to produce the resources that the population consumes and assimilate the waste that the population produces (after Wackernagel and Rees 1996).

Invasive species A species or taxon that is non-native (or alien) to the ecosystem under consideration, and whose introduction causes or is likely to cause economic or environmental harm or harm to human health (Clinton 1999; Executive Order 13112).

Urbanization Land-use conversion from agriculture or from forests, deserts, or other natural habitats for the development of homes, roads, and other facilities related to human habitation.

4.02.1 Introduction

Ecosystem services may be broadly defined as goods with direct market values, and services that maintain the production of goods and biodiversity (Daily 1997). When we think of ecosystem services, we often think of food, energy, clean water and air, and natural or semi-natural habitats that provide us with recreational opportunities, non-game wildlife habitat, and esthetic values. Charles and Dukes (2007) further define ecosystem services as:

1. Provisioning services such as food, freshwater, fiber, fuel, genetic resources, medicines, and ornamental resources;
2. Regulating services obtained by regulating ecosystem processes such as air quality regulation, flood control, water treatment, disease and pest control, pollination, erosion control, and coastal storm protection;
3. Cultural services, or non-material benefits, such as esthetic values, recreation–tourism, spiritual values, educational–scientific values, cultural heritage values, inspiration, and sense of place;
4. Supporting services that are necessary for the maintenance of the other services such as photosynthesis, primary production, nutrient cycling, water cycling, soil formation and maintenance of fertility, and atmospheric composition.

As humans have evolved and increased in numbers, they have come to directly and indirectly affect the quantity, quality, and delivery of ecosystem services from the world around them. Modern humans have roamed the planet for tens of thousands of years, but most human-caused land-use change has occurred in the past 1000 years. A recent synthesis by Goldewijk et al. (2011) reported that cropland occupied <1% of the global ice-free land area until AD 1000 (Table 1), with a similar area used as pasture lands. Croplands and pasture lands rose slowly until AD 1700, then they exponentially increased by AD 2000. Global croplands represented 11% of ice-free land in AD 2000 (15 million km^2), while pasture area increased to 24% of the ice-free land in AD 2000 (34 million km^2).

The rapid rate of land-use change is driven primarily by human population growth (Table 2). We need to eat (although our trophic position (carnivore versus herbivore) is important here).

Table 1 Global cropland and pasture area estimates for 10 000 BC to AD 2000

Year	*10 000 BC*	*5000 BC*	*AD 1*	*AD 500*	*AD 1000*	*AD 1500*	*AD 1600*	*AD 1700*	*AD 1800*	*AD 1900*	*AD 1950*	*AD 2000*

From Stohlgren, T. J., C. S. Jarnevich, and C. P. Giri, 2010: Modeling the human invader in the United States. *J. Appl. Remote Sens.*, **4,**12, used with permission.

Consider for a moment the human population of 1.6 billion in AD 1900 rising to over 6.1 billion in 2000, and the recent news that the 7 billionth person on earth was born in 2011. In this chapter, we review the implications of land-use change on ecosystem services in the broadest of ways (i.e., any aspects of ecosystems utilized (actively or passively) to produce human well-being (Boyd and Banzhaf 2007; Fisher et al. 2009)).

It is clear that the landscape is being quickly transformed. For example, it is rather obvious that agricultural land increased at the expense of natural grassland habitat and to a lesser extent of forests (Goldewijk 2001). Shrinking availability of flat, fertile croplands (Figure 1) has led to an expanding human footprint into hills and mountains (DeFries et al. 2010; Figure 2). Future demand for food may result in increased terracing, and increased conversion of mountainous forests and woodlands into agricultural fields (Table 3; Lambin and Meyfroidt 2011). Further intensification of farming practices includes increases in mechanized equipment, long-distance irrigation, and heavy reliance on fertilizers and pesticides. Thus, while one component of ecosystem services (i.e., food) gets delivered, a suite of other ecosystem services (e.g., clean air and water, plant and wildlife habitat, recreational services) may be simultaneously degraded.

Throughout this chapter, we show that the spread of humans, agriculture, and urbanization are the proximate causes of encroachment on natural areas, habitat degradation, contaminants as by-products, and the introduction of harmful invasive species around the globe.

Table 3 Estimates of land use in 2000 and additional land demand for 2030

Land use category	*Low (Mha)*	*High (Mha)*
Land use in 2000		
Cropland	1510	1611
Pastures	2500	3410
Natural forests	3143	3871
Planted forests	126	215
Urban built-up area	66	351
Unused, productive land	356	445
Projected land use for 2030		
Additional cropland	81	147
Additional biofuel crops	44	118
Additional grazing land	0	151
Urban expansion	48	100
Expansion industrial forestry	56	109
Expansion of protected areas	26	80
Land lost to land degradation	30	87
Total land demand for 2030	285	792
Balance (unused land in 2000 – land demand in 2030)		
With no deforestation	+71	−347
Clearing of natural forests	152	303
With deforestation	+223	−44

*These values were derived from the literature and selected based on an expert judgment, evaluating the realism of underlying assumptions, looking for a convergence of evidence, and using 2000–2010 observations as a reality check (references and explanations in SI Text). The low estimates represent a conservative view of both land reserve and additional land demand, whereas the high estimates represent a slightly bolder view. From Lambin and Meyfroid (2011).

Consider the rapid loss of forest cover. Forests filter our air, protect soils from erosion, and provide habitat for wildlife and pollinators. A recent study by Hansen et al. (2010) quantified gross forest cover loss from 2000 to 2005 on our planet. They found that 1 011 000 km^2 representing 3.1% of total global forest cover was lost during the 5-year period. Boreal forests suffered the largest losses, followed by humid tropical, dry tropical, and temperate forests. Brazil lost over 165 000 km^2 of forests followed by Canada at 160 000 km^2. While the remote sensing efforts could not accurately estimate recovery rates, the numbers represent alarming rates of land-use change.

Figure 2 Ready to harvest – Shengcun Rice Terracesphoto by avlxyz (public domain; http://images.cdn.fotopedia.com/flickr-2342348329-original.jpg).

In the next section, we discuss the human footprint in more detail. The prevailing themes of this chapter are to aid in the transition to sustainability of resources (Matson 2009), and to improve understanding of the potentially adverse effects of land-use change on the delivery of all ecosystem services.

4.02.2 The Increasing Urban Footprint

As the human population grows, the human footprint expands. On the surface of the world, cities cover <1% of the land, but they concentrate >50% of the population and 70–90% of economic activities (Schneider et al. 2009, 2010). This, in turn, concentrates energy use and natural resource consumption; land, water, and air pollution; and the percent of impervious surface in urban areas, which all affect ecosystem goods and services. Humans are going urban. This has not always been the case. It was not until 2008 that the global urban population exceeded the non-rural population, according to Seto and Shepherd (2009). These authors also estimate 'that by 2050, 70% of the world population will live in urban areas, with more than half of them concentrated in Asia.' Since urban land-use and land-cover changes may have considerable impacts on climate, climate records may increasingly show an 'urban heat island effect,' which is more significant during the night than day, and show greater differences in urban and rural gradients (Seto and Shepherd 2009).

However, human activities associated with trade and transportation of goods to and from urban centers create an ever-expanding web of economic activity over much broader areas. For example, Stohlgren et al. (2010) quantified changes in 'urban' 30-m cells from LANDSAT from 1992 to 2001 (**Figure 3**). They found that urban areas represented 5.1% of the lower 48 United States in 2001, but that urbanization increased 7.5% (18 112 km^2) in the 9-year period – an area the size of Massachusetts.

Interestingly, the spread of humans was easily predicted with over 92% accuracy, based on the growing degree days, elevation, humidity, and slope. Low-elevation, warm-humid areas with slopes <10% were particularly prone to conversion to urban land use. Half of the land conversions came from forests and half from agricultural lands, but both reduce, at least temporarily, ecosystem services (**Table 2**).

Forest and agricultural lands contribute most to the urban landscape, but wetlands contribute twice that of barren lands (**Table 2**). Why is this important? Direct habitat loss, especially loss of wetlands, continues to be seen as the primary cause for species decline (Stuart et al. 2004). Undisturbed wetlands provide more oxygen for us to breathe, filter more water for us to drink, and produce more wildlife for us to enjoy compared to disturbed wetlands (Tu 2009). Urbanization begets landscaping. Landscaping services have flourished generating almost $60 billion in annual sales in 2007 (Census-Bureau 2007; http://www.census.gov/econ/). Many alien species are used in landscaping, and human-dominated landscapes generally require more water, fertilizers, and pesticides to maintain. Questions remain about the direct effects of urbanization on species persistence, conservation of

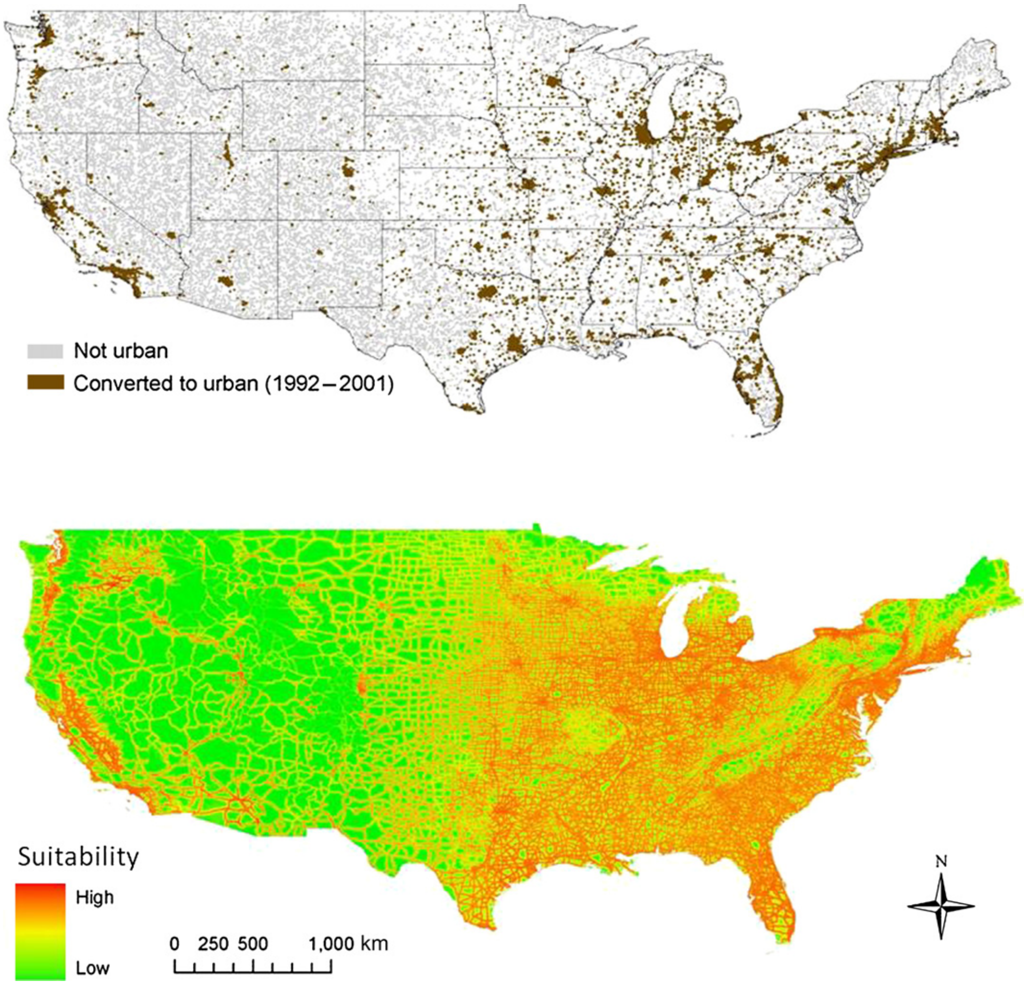

Figure 3 Rate of land-use conversion between 1999 and 2008 in the conterminous United States. Adapted from Stohlgren, T. J., C. S. Jarnevich, and C. P. Giri, 2010: Modeling the human invader in the United States. *J. Appl. Remote Sens.*, **4,** 12.

biodiversity, and climate system, but the examples described later in the chapter provide insights on the direction and magnitude of change.

4.02.3 Invasive Species and Ecosystem Services

Trade and transportation have increased over 40-fold in 100 years, reshuffling the species around the globe as geographic isolation becomes a thing of the past (Mack 2001). Alien species are now common components of floras worldwide (Stohlgren et al. 2011). Human-assisted migrations and the unintentional transportation of species will further spread alien species from local to global scales (**Figure 4**). For example, modeling the current distribution of African Fountain Grass (*Pennisetum setaceum*) helps to assess the invasive species (**Figure 4**, top) and how the habitat suitability of the species may be altered by future climate (**Figure 4**, middle). However, understanding the potential spread of the species is ludicrous without understanding, measuring, and predicting the sales and distribution of the species from commercial nurseries around the United States (**Figure 4**, bottom). Many invasive species are commercially sold and transported.

Charles and Dukes (2007) attempted to summarize the potential impacts of invasive species on ecosystem services. Unfortunately, they reported that researchers and policymakers rarely directly addressed the connection between invasions and ecosystem services. Assessments of the economic impacts of invasive species (e.g., Pimentel et al. 2005) cover control costs without directly addressing ecosystem services. Likewise, drastic changes to biodiversity are seen locally, such as the loss of bird species on Guam due to the Brown tree snake (Rodda et al. 1997), but continental-scale and global scale reports tend to be qualitative (e.g., Wilcove et al. 1998). Thus, it has been difficult to quantify the effects of invasive species on market and non-market ecosystem services.

A recent study from Europe provides an excellent model of how this problem may be addressed. Vila et al. (2010) conducted a comprehensive assessment of the impacts of alien plants, vertebrates, and invertebrates – in terrestrial, freshwater, and marine environments – on ecosystem services. They found 1094 alien species with documented ecological impacts, and 1347 alien species with economic impacts. Terrestrial invertebrates and terrestrial plants caused the greatest impacts. The North Sea was the maritime region with the greatest impacts from aquatic species. The authors also reported that across taxa and regions, ecological and economic impacts were highly correlated. Terrestrial vertebrates are responsible for the greatest range of impacts across Europe.

However, because some alien invasive species may have both positive and negative effects, there are trade-offs to consider. For example, Patel (2011) reported that *Parthenium hysterophorus*, a noxious weed from Mexico, now found in America, Asia, Africa, and Australia, can cause allergic respiratory problems, dermatitis, and genetic mutations in humans and livestock. Crop production can be greatly decreased by the competitive growth of *P. hysterophorus*, or due to its allelopathic chemicals. It also threatens biodiversity. However, *P. hysterophorus* may have health benefits for some people. It may be 'a remedy for skin inflammation, rheumatic pain, diarrhea, urinary tract infections, dysentery, malaria, and neuralgia,' according to Patel (2011), so the plant's positive aspects must be evaluated along with its negative aspects.

Bees provide another example of trade-offs to consider. Alien bee species aid in pollination, but the Africanized honey bee is a danger to human health. Many alien fish species provide recreational opportunities, but they may transmit whirling disease to native fishes. Alien zebra mussels may filter water, but they may also clog pipes cooling nuclear power plants. Alien shrubs, such as tamarisk, may provide some local habitat for threatened and endangered species, such as the southwest willow flycatcher (York et al. 2011). However, the invasive tamarisk may cause other problems such as increased fire risk, soil salinization, and pre-emptive water use in arid systems (Zavaleta 2000). Charles and Dukes (2007) conclude:

> Virtually all ecosystem services can be negatively impacted by invasive species, although positive impacts do exist. Many invasive species cause cascading effects in communities and/or affect both biotic and abiotic components of ecosystems. This usually leads to an influence on multiple ecosystem services.

4.02.4 Additional Effects of Land-Use Change

Direct effects of land conversions include direct loss of habitat generally causing many potentially negative effects to ecosystem services. However, there are indirect effects too. In this section, we discuss declines in habitat quality, potential effects of habitat fragmentation, altered disturbance regimes, livestock grazing, road building, and water storage and diversions needed to support our growing population.

4.02.4.1 Declines in the Quality of Natural Habitats and Habitat Fragmentation Effects

Declines in habitat quality can occur when forests are converted from old growth forests to second growth forests, especially for old-growth-dependent species such as the marbled murrelet (*Brachyramphus marmoratus*), northern spotted owl (*Strix occidentalis caurina*), and red-cockaded woodpecker (*Picoides borealis*), which are often prized by conservationists. There is conventional wisdom that small, isolated wildlife populations are more susceptible to extirpation and extinction (Gilpin and Soulé 1986), so the impacts of land-use change on habitat loss, habitat fragmentation, and loss of connectivity of sensitive habitats may combine to increase extinction rates of species of concern to society. The direct effects of land-use change are easily measured, such as the loss of over 50% of the wetlands in the United States since AD 1600 (http://water.epa.gov/type/wetlands/vital_status.cfm). Declines in habitat quality are more difficult to measure. However, land use has clearly affected habitat quality for numerous species and particularly many old-growth dependent species (Kerley et al. 2011 for a review).

The effects of habitat fragmentation have been poorly measured to date. Fahrig (2003) reported that empirical studies suggest that habitat loss has large, consistently

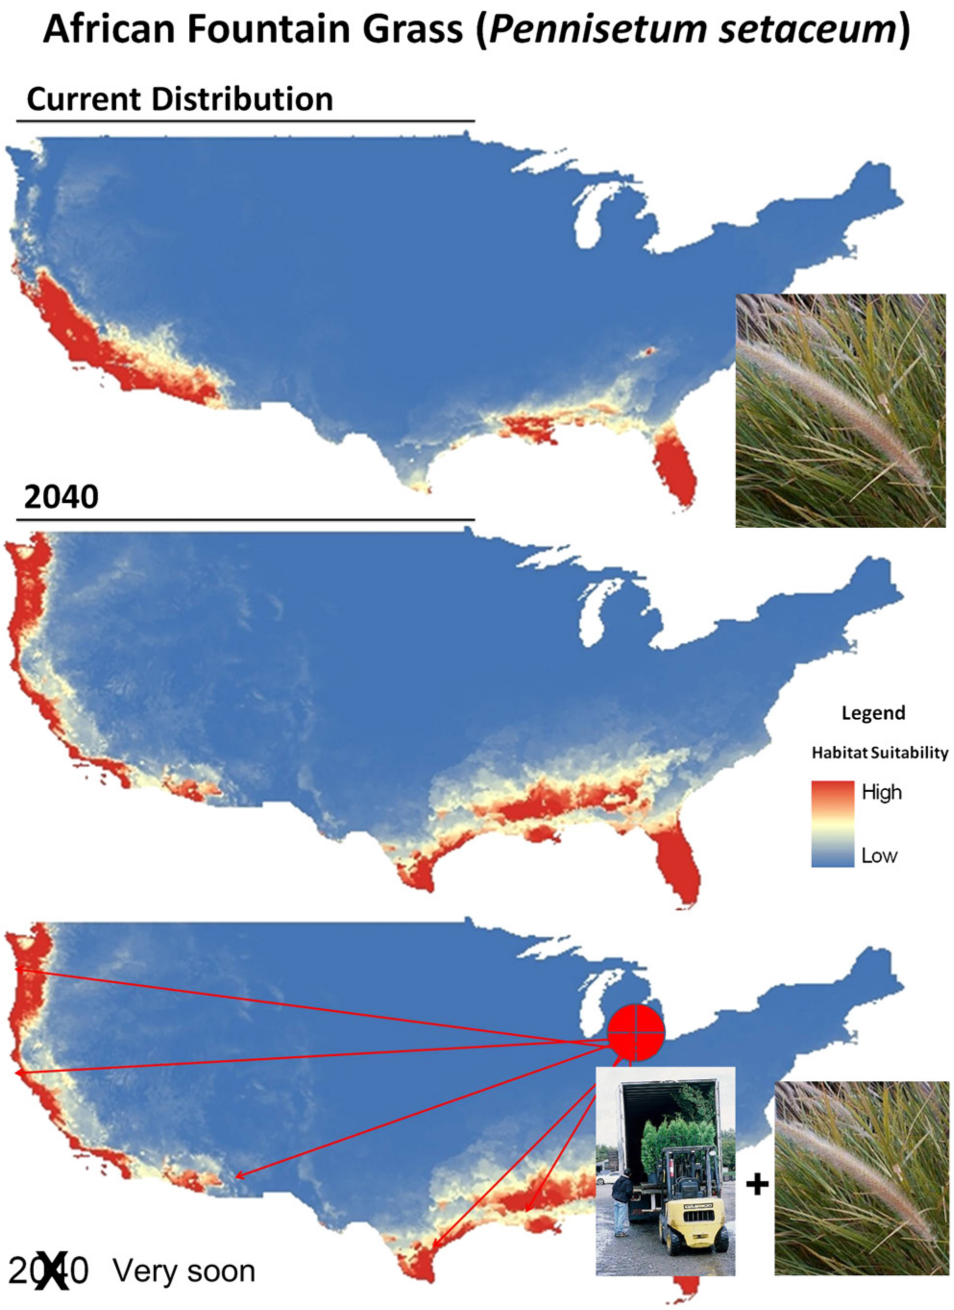

Figure 4 Modeling the current distribution of an invasive species African Fountain Grass (*Pennisetum setaceum*) (top), a potential future distribution of the species given a future climate change scenario (middle), and the hypothetical spread of the species because it is sold in commercial nurseries around the United States (bottom).

negative effects on biodiversity, but that habitat fragmentation per se has much weaker effects on biodiversity, and such effects may be positive or negative. Additional research might be better focused on the more direct effects of habitat loss (Hodgson et al. 2011).

4.02.4.2 Widespread Grazing of Domestic Livestock

Grazing lands in the Unites States cover more than 350 million ha, generate $40 billion in income, and maintain over 100 million livestock (Krueger et al. 2002), but there have been no complete, quantitative assessments of the cumulative effects of grazing on ecosystem services. It is a complicated issue because of the many positive and potentially negative economic and environmental effects, strong social pressures, and politically sensitive underpinnings. The qualitative overview by Krueger et al. (2002) discusses positive aspects of grazing related to maintaining rural economies, reducing wildfire fuels, and managing ‘desirable’ vegetation communities. The review also discusses environmental impacts on soil, water quality, riparian areas, and biodiversity, including invasive plant species. Several site-specific studies cited in the report show that livestock affect soils via compaction, erosion, and changes in the plant community; and water quality via manure and urine inputs. However, we found no comprehensive qualitative assessments of livestock grazing, despite the obvious need.

4.02.4.3 Road Building

Roads and roadsides cover less than 1% of the United States, but the 6.2-million-kilometer system connects every city and town and infiltrates every county (Forman and Alexander 1998). Negative ecological impacts associated with roads include erosion, altered hydrological systems, microclimates, and conduits for harmful invasive plants, animals, and diseases. The effects of roads can be measured from meters to kilometers away from the physical feature. As described by Forman and Alexander (1998), roads can have a great effect on wildlife. Road kill is a common source of wildlife mortality. Meanwhile, road avoidance by wildlife can also alter migration patterns and the genetics of populations. That 1% direct loss in natural vegetation habitat by road building may actually affect 15–20% of the land in the United States.

Roads are major corridors of invasion. For example, Gelbard and Belnap (2003) found that roads were a large contributor to the spread of alien grasses and forbs in the semiarid grasslands, shrublands, and woodland communities of southern Utah, United States. The cover of *Bromus tectorum* (cheatgrass) was three times as great along roads compared to non-road interior areas. Other alien plants, animals, and diseases are likely facilitated by transportation networks. As with the issue of grazing, a comprehensive, quantitative assessment on the effects of roads is badly needed.

4.02.4.4 Water Control – Dams, Diversions, and Irrigation

The scope of this land-use effect is difficult to fathom (pun intended). It is estimated that 77% of the total discharge of the 139 largest river systems in the northern third of the world is affected by dams, diversions, and irrigation (Dynesius and Nilsson 1994). Many rivers now fail to reach the sea in many years, including the Nile River in Africa, and the Colorado River in the United States, largely to meet food production demands (Postel 1998). Dams provide energy, and reservoirs provide water, but there are mounting ecological impacts from human-altered hydrology. Reservoirs have become refuges for sediments, chemical waste, and invasive alien fishes and plants. According to Postel (1998, p. 636), "Large dams and river diversions have proven to be primary destroyers of aquatic habitat, contributing substantially to the destruction of fisheries, the extinction of species, and the overall loss of the ecosystem services on which the human economy depends. Their social and economic costs have also risen markedly over the past two decades." However, much more quantitative work is needed to fully assess the cumulative positive and negative effects of dams, diversions, and irrigation on ecosystem services (see http://www.nationalrivers.org/node/490inter).

4.02.4.5 Wildfire, Fire Suppression, and Managed Fires

Many natural disturbances such as volcanic eruptions, hurricanes, tornados, floods, insect outbreaks, and wildfires affect ecosystem services. We report on wildfire, fire suppression, and managed fire in the United States as an example of the effects of the disturbance of ecosystem services because (1) humans have had a large effect on the location and size of fires as either the source of ignition or in suppression efforts and (2) the direct and indirect effects of fire can be substantial on local and regional air quality, water quality, carbon storage, wildlife habitat, esthetics, and human health.

Fires in the 1900s in the United States were sporadic and patchily distributed. There were extensive wildfires in the 1930s. The decline in land area burned since the late 1950s has been attributed to wildfire awareness campaigns (e.g., Smokey Bear) and the advent of effective ground-based and aerial fire suppression coordination. According to the National Interagency Fire Center website, between 1983 and 2010, almost 50 million hectares burned, with an average of almost 1.8 million hectares burned per year (http://www.nifc.gov/fireInfo/fireInfo_stats_totalFires.html). Despite costs to property and human health, natural fire is important to the regeneration of many forest types in the United States, and is a valuable process in maintaining ecosystem function (Arno 2000). However, fire suppression may be affecting a greater land base than wildfire.

Fire suppression is a dual-edged sword. While it protects the current crop of vegetation, which stabilizes soils, filters air, and provides for wildlife habitat and recreational, continued fire suppression results in buildup of fuels and sets the stage for potentially catastrophic fires later. Managed fire produces smoke, resulting in air quality issues, but it may save lives and property, albeit with some risk, especially at the urban–wild land interface. Much like terracing in agriculture, urban development is spreading further into fire-prone areas (e.g., chaparral in California, pine woodlands in Colorado). Fire ecologists are just now beginning to take a comprehensive look at the effects of fire suppression on natural systems and the urban–wild land interface (Davis et al. 2010).

In addition to human encroachment into fire-prone areas, fire management tools such as forest thinning, clearing around structures, and use of prescribed burning all carry risks for human safety. Post-fire activities such as seeding with alien grasses, or the natural spread of alien grasses, may increase the frequency and intensity of wildfire in fire-prone communities (Hunter et al. 2006). Humans demanding privacy, natural settings, and fire protection may not get them all.

4.02.4.6 Use of Fertilizers, Pesticides, and Herbicides

Land-use changes into agriculture or urban landscaping generally cause an increase in the use of fertilizers, pesticides, and herbicides. Tilman (2001) estimates that during the next 50 years of rapid agricultural expansion, demand for food will be a major driver of global environmental change with 10^9 ha of natural ecosystems to be converted to agriculture by 2050. This, in turn, may cause 2.4- to 2.7-fold increases in nitrogen and phosphorus application and further eutrophication of terrestrial, freshwater, and near-shore marine ecosystems. He predicts similar increases in pesticide use.

Increased use of water (and energy) to support agriculture and urban landscapes provides the mechanism for the eutrophication of streams and rivers. 'Eutrophication' is the enrichment of surface waters with plant nutrients (http://www.fao.org/docrep/w2598e/w2598e06.htm). Agriculture is often seen as a major contributor to the eutrophication of surface waters. An obvious trade-off exists between the need to feed an ever-growing human population and the need to maintain water quality and the many other ecosystem services derived from streams and rivers with high environmental integrity (Matson Robertson and Swinton 2005).

4.02.4.7 Other Indirect Effects of Land Use

There are many by-products of land-use change. Beyond the human footprint is an ever extending zone of influence. Pets escaping, such as dogs and cats affecting local bird populations (Leu et al. 2008), but escapes of more insidious pets such as Burmese pythons in Florida, or aquatic weeds and disease carrying snails from aquaria are other examples of indirect urbanization effects. Factory and energy plant smokestacks and car exhaust pipes send air pollution around the globe. We facilitate dust storms that bridge continents with land-use decisions. Abandoned mines continue to leak heavy metals into domestic water supplies. New types of energy development, such as fracking for oil and gas, are already creeping beneath urban and suburban homes. We see sewage treatment plants and landfills at the edge of town, but rarely view our refuse dumped in the bottom of the ocean. We store nuclear waste below ground, and space junk orbits in the skies above. The ecosystem service furthest from our minds is disposal.

4.02.5 Challenges and Solutions

Lambin and Meyfroidt (2011) found that economic globalization accelerates land conversion. This creates a challenge in delivering ecosystem services, while reducing the harmful effects of deforestation, contaminants associated with agriculture and urbanization, and the accelerated exchange of harmful alien species – plants, animals, and diseases. Local solutions may include carefully adapting agricultural intensification to reduce the use of fertilizers, pesticides, and water (Ahrens et al. 2010). Regional to national solutions include land-use zoning, forest protection, an increased reliance on imported food and wood products, the creation of off-farm jobs, and foreign capital investments (Lambin and Meyfroidt 2011). Increasing land use will not be easy in many cases, since social aspects and local economic forces may slow progress (Matson 2009).

A key endeavor for conservation may be to focus on minimizing direct habitat loss, especially the direct losses of the habitats for rare, endangered, or threatened species. Attention to the proximate causes of change: overpopulation, demand for resources, unsustainable agriculture and forestry practices may provide a good place to start. The connections are clear and unambiguous. Human population increase will lead to additional agriculture, a decrease in biodiversity, and an increase in the use of pesticides and herbicides that will affect all ecosystems surrounding the agricultural land (Tilman et al. 2001).

Managing the increasing human footprint is important. We need to more accurately quantify the cumulative effects of agriculture, deforestation, road building, and urbanization (Leu et al. 2008). Prime consideration for conservation areas may be based on the rarity of habitat, unique species assemblages in those habitats, and potential for persistence of

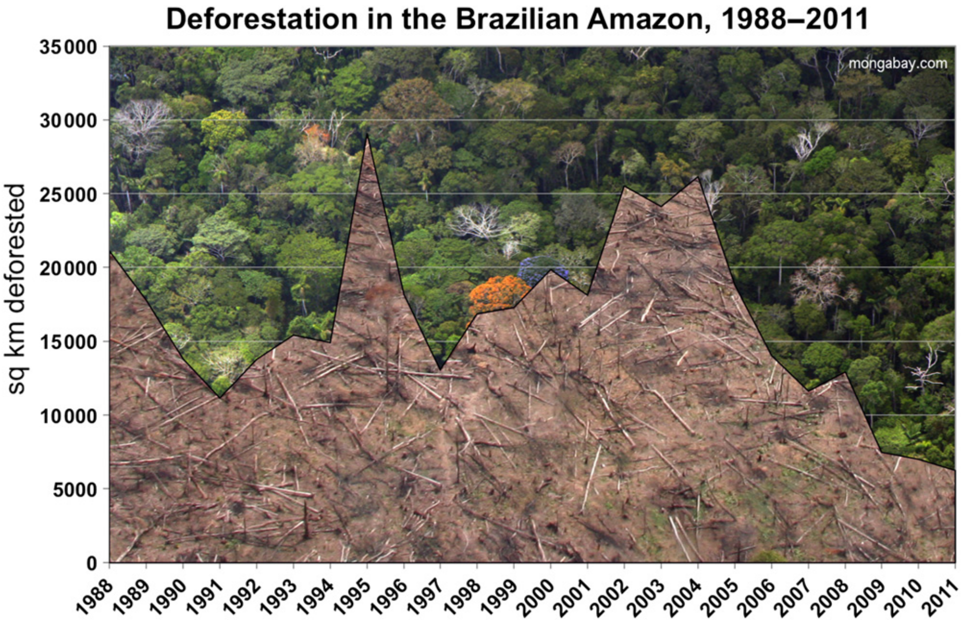

Figure 5 Deforestation in the Brazilian Amazon. http://www.mongabay.com/brazil.html.

ecosystem services from those rare types under different management scenarios.

Sustainable development will include trade-offs. Unconstrained human population growth may result in difficult choices – whether to build atop prime agricultural lands or further into natural, semi-natural, or fire-prone habitats. The water and energy needs of a growing or spreading population must prepare for occasional long-term droughts. Long-range conservation planning is essential. We need accurate forecasts and scenarios to guide sustainable land use (Turner et al. 2007; Wirsenius et al. 2010).

Trade and transportation have increased 40-fold in our lifetime (Stohlgren et al. 2011). Many harmful plants, animals, and diseases will accompany future changes in land use and climate. Balancing trade-offs and a triage of research needs will be necessary. Regional and local changes in climate statistics may play a role, but it will be slower and more long term, and less so a proximate driver of change to ecosystem services relative to direct habitat loss and invasive species.

Economics drives land-use change. Deforestation in Brazil (**Figure 5**) is driven by industrial agriculture and land speculation, with more than 70% of deforested land ending up as cattle pasture. It is these high commodity prices that create incentives for deforestation.

In the end, it may come down to engineering better solutions to sustain life and ecosystem services (e.g., Matlock and Morgan 2011). More people will create a greater demand for resources. Increased demand for resources will affect habitat quantity and quality, unless we manage land use wisely. Difficult decisions will require the best data and predictive models available. We have to ask ourselves, ‘How much are we leaving for future generations to ensure quality ecosystem services in the future?’ In the words of Chief Seattle:

> Humankind has not woven the web of life. We are but one thread within it. Whatever we do to the web, we do to ourselves. All things are bound together. All things connect.

Glossary

Critical loads The input of a pollutant below which no known detrimental ecological effects occur over the long term.

Ecosystem services Outputs of ecological functions or processes that directly or indirectly relate to human well-being.

Reactive nitrogen Includes all forms of biologically, chemically, and radiatively active nitrogen compounds in the atmosphere and biosphere.

4.03.1 Introduction

Nitrogen (N) is an essential element required for life, but availability of N often limits primary production in terrestrial and aquatic ecosystems (Elser et al. 2007; LeBauer and Treseder 2008). Human population growth and increased demands for energy, transportation, and food, combined with technological advances, have lead to increased N fixation (Townsend et al. 2003; Galloway et al. 2008). A substantial fraction of the reactive N used for human needs is eventually transferred to the environment. Nitrogen cycling is accelerated by human activities through the application of fertilizers, the cultivation of N_2-fixing crops such as soybeans, the combustion in power plants and vehicles, and through disposal and treatment of human and animal wastes.

N release to the environment during the last century has more than doubled globally, fundamentally altering ecosystem structure and function in many places (Vitousek et al. 1997; Davidson et al. 2012). Nitrogen deposition continues to reduce biodiversity of native ecosystems and increase the dominance of invasive species (Bobbink et al. 2010). Nearly two million Americans live in homes where the well water contains nitrate concentration at or above the drinking water standard for human health (Compton et al. 2011). Currently, many streams in the United States are in poor condition due to excess nitrogen (Paulsen et al. 2008). Many lakes and terrestrial ecosystems exceed critical loads, defined as the input of a pollutant below which no known detrimental ecological effects occur over the long term (Baron et al. 2011; Pardo et al. 2011). Increases in reactive N mobilization have increased the production of N_2O, a greenhouse gas, and also now the dominant chemical that destroys the protective ozone layer (Davidson 2009; Ravishankara et al. 2009). Nitrogen loading alters the production of CH_4 and CO_2 in complex ways and contributes to particulate-driven cooling, and, as such, has the potential to warm and cool the climate (Davidson et al. 2012). Anthropogenic increases in N deposition have now been observed in even extremely remote high arctic lakes (Holtgrieve et al. 2011). Reactive N continues to have broad impacts on ecosystems and human health despite improvements in the scientific understanding of N loading and effects on the environment (Sutton et al. 2011; Davidson et al. 2012).

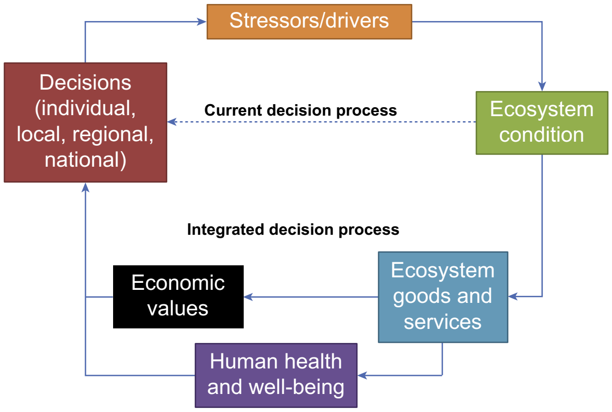
These fundamental changes to ecosystem structure and function in turn have altered key ecosystem services such as the provision of clean air and water, recreation, fisheries, forest products, esthetics, and biodiversity (Table 1). The Millennium Ecosystem Assessment (MA 2005) underscored that understanding the trade-offs inherent in controlling this class of environmental pollutant is one of the major challenges to be faced in the twenty-first century. The damages caused by this unintentional release of N from industry, agriculture, and transportation to the environment are considered externalities and are not included in the costs of nitrogen use (Kusiima and

Table 1 Ecosystem services and human benefits affected by increasing N deposition

Ecosystem service	*Direction of impact*	*Mechanism of impact on human benefit*
Production of food and materials	+	Increased production and nutritional quality of food, wood, and fiber crops during the last century
	+	Increased production of building materials and fiber for clothing or paper
	–	Stimulate ozone formation, which in turn can reduce agricultural and wood production
	–	Soil acidification, nutrient imbalances and altered species composition, and diversity in natural ecosystems, ultimately impacting stability and resistance to disease, weather extremes, invasive species, and fire
Fuel production	+	Increased use of fossil fuels to improve human health and well-being across the globe
	+/–	Increased N inputs required for some biofuel crops can affect other services
Clean air	–	Increased particulates (from NO_x and NH_x), which exacerbate respiratory and cardiac conditions
	–	Increases in ozone (NO_x-driven), which exacerbate respiratory and cardiac conditions
	–	Increased allergenic pollen production
Drinking water	–	Increased nitrate concentrations lead to blue baby syndrome, thyroid issues, and certain cancers
	–	Increased acidification and mobility of heavy metals and aluminum
Swimming	–	Stimulated harmful algal blooms that release neurotoxins (interaction with P)
	–	Increased vector-borne diseases such as West Nile, malaria, and cholera
Fishing	+	Increased fish production and catch for some very N-limited coastal waters
	–	Increased hypoxia and harmful algal blooms in coastal zones, closing fish, and shellfish harvests
	–	Reduced number and species of recreational fisheries from acidification and eutrophication
Hiking	–	Altered biodiversity, health, and stability of natural ecosystems
Climate regulation	+/–	Variable and system-dependent impacts on net CO_2 exchange
	–	Stimulate N_2O production, which is a powerful GHG
UV regulation	–	Increased N_2O release, which has strong ozone-depleting potential
Visibility	–	Increased NO_x in air stimulates formation of particulates, smog, and regional haze
Cultural and spiritual values	–	Altered biodiversity, food webs, habitat, and species composition of natural ecosystems
	–	Damage to buildings and structures from acids
	+/–	Harmful effects of N in countries distant from emission sources and some of the benefits, due to long-distance transport of N and globalization of industries and agriculture

Modified from Compton, J. E., J. A. Harrison, R. L. Dennis, T. L. Greaver, B. H. Hill, S. J. Jordan, H. Walker, and H. V. Campbell, 2011: Ecosystem services altered by human changes in the nitrogen cycle: a new perspective for US decision making. *Ecol. Lett.*, **14,** 804–815.

Powers 2010). An approach that explicitly examines ecosystem services and human well-being (Figure 1) could focus and augment more traditional approaches, which have had limited success and left us with continuing nutrient problems (US EPA 2009).



Stressors/drivers
Decisions (individual, local, regional, national)
Current decision process
Ecosystem condition
Integrated decision process
Economic values
Ecosystem goods and services
Human health and well-being

Figure 1 Current decision process generally incorporates response of ecosystem condition (e.g., concentrations, process rates, fluxes, species composition) to anthropogenic stressors and drivers, while an integrated decision process incorporates information about the impacts on ecosystem goods and services, human well-being, and economic values.

The goals of this chapter are to (1) review the state of the science connecting increasing N deposition to ecosystem services, (2) identify knowledge gaps in our understanding of the impacts of N deposition on ecosystem services, and (3) discuss the expectations and research needed to effectively connect ecosystem services science to policy into the future.

4.03.2 Defining an Ecosystem Services Approach

Ecosystem services are the aspects of nature that benefit people. Daily et al. (2009) define ecosystem services as the "conditions and processes through which natural ecosystems and species therein sustain and fulfill human life or have the potential to do so in the future." The Millennium Ecosystem Assessment (MA 2005) categorized services into provisioning, supporting, regulating, and cultural services. Others have refined this definition to improve the applicability of ecosystem services for decision-making, as outputs of ecological functions or processes that directly or indirectly relate to human well-being (Fisher et al. 2009). For the purposes of this chapter, an ecosystem services approach is defined as connecting human benefits to ecological structure and function, allowing for quantification of positive and negative impacts of decisions, being as complete as possible in quantifying the scope of impacts, and including an economic

Campbell, 2011: Ecosystem services altered by human changes in the nitrogen cycle: a new perspective for US decision making. *Ecol. Lett.*, **14,** 804–815.

valuation component. For example, prior to a decision related to a new regulation, such as a new air policy or a total maximum daily load (TMDL) for a stream reach, the costs and benefits of the decision are assessed. In general, the direct human health impacts have been well studied but the information on ecosystem impacts and connections to ecosystem services are often not suitably well understood to inform policy. This chapter attempts to make more of these connections and to identify gaps where we know there are effects but those effects are not well studied or connected to the driver, N load. We also discuss valuation of the costs or impacts where possible.

Figure 2 illustrates the links between N sources, N cycling, ecosystem services, and benefits to people. Many of the effects on structure and function alter the production of ecosystem services, such as the provision of food, water and materials, regulation of climate and UV protection, provision of clean air, and habitat and biodiversity for recreation and human well-being. Changes in ecosystem services alter the benefits for people, influencing air for breathing, visibility, esthetics, water for drinking, recreation, and a host of other services.

4.03.3 Connecting Effects on Ecosystem Structure and Function to Ecosystem Services

In the following section, we focus on several sets of key ecosystem services that directly link to management of N in the environment: (1) provision of clean air and water for direct human needs, (2) food, fuel, and fiber production, (3) maintenance of biodiversity and esthetics, and (4) climate regulation. This does not include all services potentially impacted by nitrogen deposition, but represents a number of key services. In some cases, much is known about the impacts on ecosystem structure and function, but the connection to ecosystem services and benefits to people may not yet be clear in the literature (see Figure 2). In those cases, this review attempts to connect the impacts on structure and function to services and benefits. In some cases, the impacts have been studied all the way through to economic valuation, and we are able to compare the relative impacts of nitrogen on these values with a simple metric of dollars per kg N ($/kg N). See Compton et al. (2011) for more detail on valuation of costs associated with reactive nitrogen. The EU Nitrogen Assessment (2011) also used this metric in their analysis on the costs and benefits of impacts.

4.03.3.1 Provision of Clean Air and Clean Water for Direct Human Needs

Tremendous benefits to human health and well-being have resulted directly or indirectly from human alteration of the N cycle, particularly in terms of nutrition, materials (e.g., wood, paper, fabric), and provision of heat, light, and transportation. Many of these positive impacts can be tracked through economic indicators. However, when N is transported downwind or downstream from sites where its use is primarily beneficial to humans, it can become a hazard to human health (Townsend et al. 2003). These detrimental impacts are more challenging to track and do not necessarily correlate with the benefits (Raudsepp-Hearne et al. 2010).

Air quality and consequent health effects strongly respond to changes in reactive N. NO_x is an important precursor of tropospheric ozone and particulate matter (with NH_x), which can increase rates of asthma and other respiratory issues, particularly in children and other vulnerable populations (Delucchi 2000). While many of these interactions occur in the atmosphere, the net resulting air quality is a result of interactions between atmosphere, biosphere, and hydrosphere, and, thus, the provision of clean air is considered to be an ecosystem service. On an annual basis, particulate exposure is estimated to cause nearly 130 000 premature deaths and ozone exposure another 7000 deaths, and there are thousands of hospital visits and other well-being issues related to respiratory issues triggered by reactive N (Davidson et al. 2012).

The provision of clean water for drinking and other domestic uses is a key ecosystem service, and unfortunately nitrate contamination in drinking water is a growing issue in the United States. The number of drinking water violations of the nitrate standard in community drinking water wells nearly doubled between 1998 and 2008 (US EPA 2009). Excess nitrate in drinking water has been associated with a number of illnesses, including blue baby syndrome and several types of cancers (Townsend et al. 2003; Ward et al. 2005). Although nitrate contamination of drinking water has an important and growing impact on this vital ecosystem service, atmospheric deposition does not generally lead to groundwater nitrate contamination. Instead, Agricultural fertilizer inputs are the dominant driver for groundwater contamination with nitrate, and atmospheric deposition is not a broadly important factor (Nolan et al. 2002).

Excess N in surface waters can have indirect effects on human health by stimulation of harmful algal blooms (HABs) that produce toxins (Camargo and Alonso 2006), outbreaks of dangerous pathogens, like *Cryptosporidium*, or simply unpleasant odors and tastes that are costly to remove. Even where nitrate concentrations are below the US EPA drinking water standard (10 mg nitrate-N l^{-1}), nitrate and eutrophication can increase treatment costs needed to create safe drinking water. Some treatment processes designed to remove the products of eutrophication can introduce harmful chlorination byproducts into drinking water (Cooke and Kennedy 2001). There is also some suggestion that N enrichment can exacerbate pathogens such as West Nile virus, pollen allergens, swimmer's itch, malaria, and cholera (Townsend et al. 2003; Johnson et al. 2010).

The costs of human health problems related to N have been evaluated in a number of studies and have generally been found to be the most costly impacts in a relative (per unit N) and absolute sense. In a detailed review of the valuation of air quality regulations on humans and ecosystems, mortality and illness associated with reactive N forms as precursors to PM and ozone were the most substantial of the measured effects (Chestnut and Mills 2005). A number of US and EU studies have also examined the cost of NO_x and NH_y effects on respiratory health; most recently the ExternE project determined the health impacts of reactive N in air to be $28 per kg NO_x-N and $16 per kg NH_3-N (Bickel and Friedrich 2005). Even in the Chesapeake Bay, where N deposition is not the largest source of N, the human health consequences of nitrogen forms in air had the highest quantifiable damage costs because of the high value placed on human health (Birch et al. 2011). Interactions of increased reactive N in the atmosphere through the multiple forms and by-products of nitrogen (ozone and particulates), biosphere, and hydrosphere clearly have profound impacts on human health and in turn well-being.

At certain levels of N loading, ecosystem services can actually mediate N impacts, particularly the provision of clean water for drinking. Plants, microbes, and soil organic matter can remove some of the added nitrogen along flow paths in soil, streams, and groundwater, serving as sinks for excess reactive N, providing an important ecosystem service that would cost several dollars per kg N in a sewage treatment plant. In particular, wetlands have significant capacity to remove N (Jordan et al. 2011). In some cases, large increases in reactive N can reduce the N storage capacity or uptake kinetics of these ecosystems (Perakis et al. 2005; Mulholland et al. 2008). One of the potential costs of reactive nitrogen is this reduction in the ecosystem services of water purification; however, we are not aware of an analysis that explicitly examines these costs.

4.03.3.2 Impacts on Food, Fuel, and Fiber Production

Because temperate ecosystems are often limited by the availability of reactive N, biological production can be increased by N additions in these systems. The broad benefits of N fertilization on food and material production are well known, particularly for agriculture, but the damages to these services caused by increasing N in the environment are not as well understood. Several studies have quantified damage costs of N on food and fiber production. One of the most complete national analyses of N deposition effects examined the consequences of US air pollution control policies (Chestnut and Mills 2005). Emissions of N and S oxides led to acidification and damage to materials that cost approximately $133 million annually prior to the US Acid Rain Program, 1990 Clean Air Act Amendments (Chestnut and Mills 2005). Nitrogen oxides also contribute to ozone formation in the troposphere, which can reduce crop and forest production in ways that could offset any fertilization effects, particularly in areas where N loading is already high. Ozone reductions projected to result from the 1990 Clean Air Act Amendments were estimated to provide a total annual benefit to the US commercial timber industry of about $800 million, and improved yields were estimated to benefit grain crop producers by $700 million in 2010 (Chestnut and Mills 2005). Increases in N also fuel UV damages to crop production and fisheries/corals, since N_2O is currently the most important contributor to the breakdown of stratospheric ozone (Ravishankara et al. 2009), although N deposition plays a small role in N_2O production.

There are some potential trade-offs between harmful and beneficial effects. While ozone and acidification may reduce productivity, increases in the availability of N (a limiting nutrient) may increase production of a particular species or groups of species. Thomas et al. (2010) clearly demonstrated that most tree species had faster growth rates as deposition increased over space in the northeastern United States, using an analysis of repeated sampling of forest inventory plots (**Figure 3**). The approximate enhancement in carbon gain was 40% above preindustrial N deposition at levels up to 11 kg N ha^{-1} yr^{-1}. While it is not clear what the net effect of these increases in productivity will be for timber production,

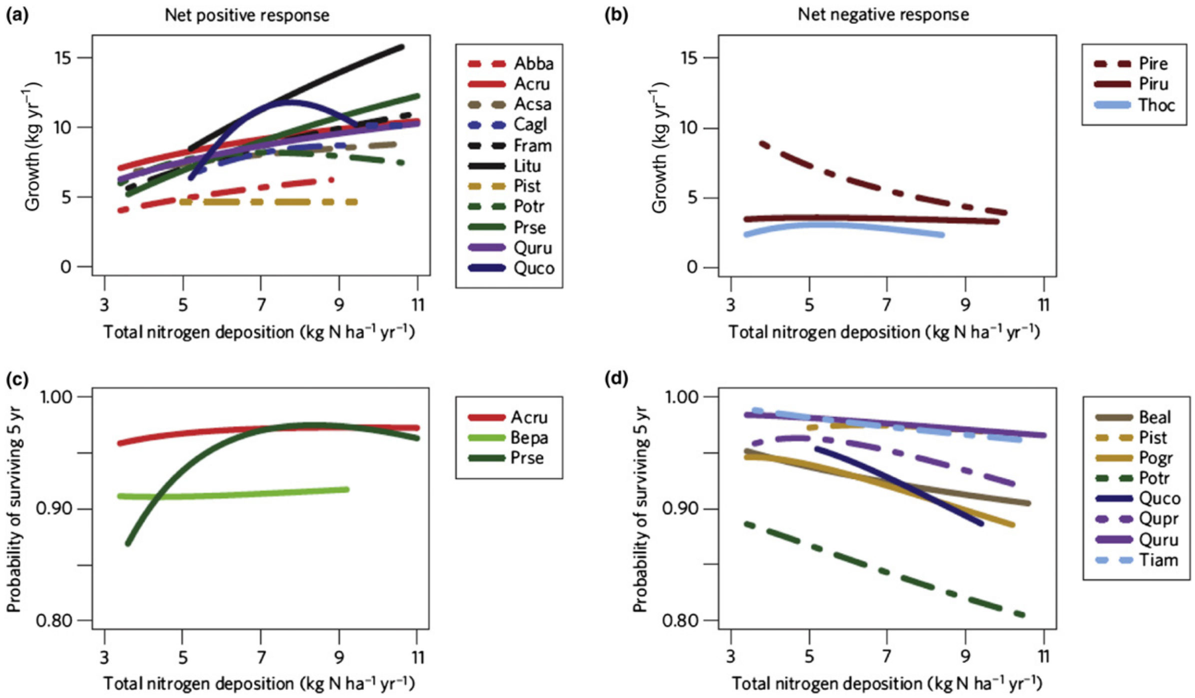

Figure 3 Growth and survival response to increasing N deposition. Annual above-ground carbon increment (a–b) and 5-year survival rate (c–d) as a function of total (wet C dry) inorganic N deposition for individual trees of the 24 most common species in a 19-state region of the eastern United States *(see original paper for species codes). Species that did not respond to nitrogen deposition are not shown.* Reproduced from Thomas, R. Q., C. D. Canham, K. C. Weathers, and C. L. Goodale, 2010: Increased tree carbon storage in response to nitrogen deposition in the US. *Nat. Geosci.*, **3,** 13–17.

the species with the largest positive growth responses were the valuable timber species tulip poplar and black cherry. By stimulating plant production, N inputs from atmospheric deposition may account for a significant fraction of current terrestrial C uptake in some systems (Liu and Greaver 2009). Productivity of grasslands and alpine ecosystems has also been shown to increase with N deposition, but is accompanied by a decrease in biodiversity (Bowman et al. 1995). We discuss this impact on biodiversity in a later section. Clearly an N-driven increase in terrestrial productivity could have important implications for timber production and other terrestrial products, but the net impacts and economic implications have not been broadly quantified.

In aquatic ecosystems, increasing N loads can also stimulate production, particularly in estuaries and near-coastal waters, but the relationship is not linear. At low N loading, fisheries may be limited by N, whereas increasing N loads can lead to eutrophication, hypoxia, and anoxia with the potential to reduce fish production (Breitburg et al. 2009). Acidification of sensitive surface waters can impact fish species composition (see biodiversity section below for more discussion). The desirability of enhanced production of any given species is somewhat variable: for example, greater algal production could ultimately lead to fish kills; atmospheric N loading could stimulate the production of undesirable or exotic species (e.g., Suding et al. 2004) leading to questions about how various increases in production should be valued. Despite the complexities, greater understanding of how to value the net benefits or detriments of N loading to the environment would significantly contribute to our understanding and ability to implement an ecosystem services approach to management of the environment and natural resources.

Harmful algal blooms and fish kills linked to N or other nutrients have caused substantial losses to the seafood industry. Whitehead et al. (2003) estimated that the lost consumer surplus due to a dinoflagellate (*Pfiesteria* sp.) related fish kill is between \$37 and \$72 million in the month following a fish kill. Production of shrimp and crabs in Gulf estuaries is large and sensitive to habitat loss (Jordan et al. 2009), and damage to this valuable fishery was one of the highest per kg N damages identified by Compton et al. (2011). However, more data on fisheries valuation impacts from reactive N are needed.

4.03.3.3 Maintenance of Biodiversity and Esthetics

Excess N has been repeatedly shown to reduce the biodiversity of natural ecosystems. A recent global analysis found that N deposition is the main driver of altered species composition in a range of ecosystem types (Bobbink et al. 2010). Species that tend to show increases in abundance are often non-native invasives with high vegetative and population growth rates, which have the potential to drive local populations of rare native species to extinction (Bobbink et al. 2010). Figure 4 shows the relationship between N deposition and declining biodiversity in European grasslands (Stevens et al. 2010).

The linkages between biodiversity and benefits to people are clear. Balvanera et al. (2006) review the impacts of biodiversity of ecosystem services, which include productivity, nutrient cycling, erosion control, and ecosystem stability (Figure 5). Ecosystem services associated with biodiversity can be

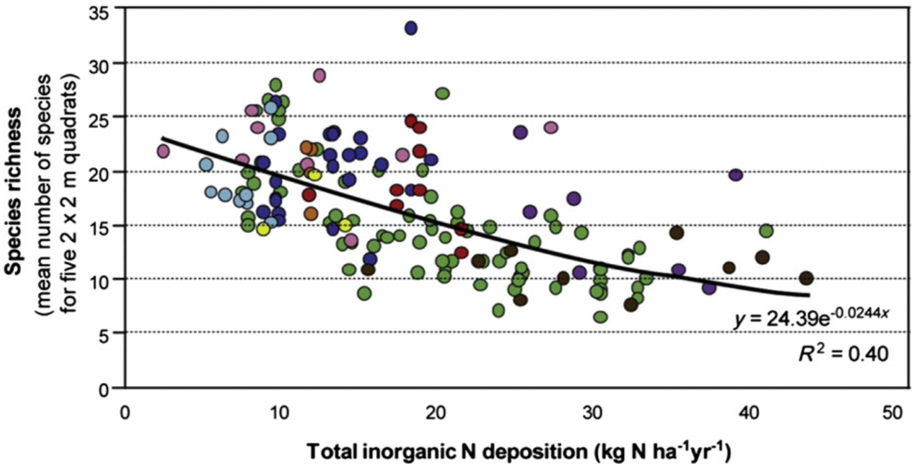

Figure 4 Nitrogen deposition reduces grassland biodiversity for x plots across Europe. Total plant species richness (mean number of species in five 2 × 2 m quadrats per site) against total inorganic N deposition for each of the countries surveyed: Belgium (red), Denmark (yellow), France (dark blue), Great Britain (green), Germany (brown), Ireland, Northern Ireland and Isle of Man (pink), the Netherlands (purple), Norway (turquoise), and Sweden (orange). The curvilinear relationship between N deposition and species richness is shown. From Stevens, C. J., and Coauthors, 2010: Nitrogen deposition threatens species richness of grasslands across Europe. *Environ. Pollut.*, **158,** 2940–2945.

challenging to estimate value, but the linkages are clear between biodiversity and key supporting ecosystem services. The provision of habitat for organisms which influence the integrity, resilience, spiritual value, and beauty of the natural world is an important service (e.g., Losey and Vaughan 2006). In addition, N-driven changes in biodiversity can influence nutrient losses and influence fire frequencies (Tilman et al. 1996; Rao et al. 2010), which have important economic and human health consequences.

Ecosystem acidification via atmospheric N deposition is another driver of species change. Sulfur deposition has also been an important driver of acidification and so this discussion includes the effects of both since they are so strongly related. Following deposition, sulfate and nitrate anions can leach out of soils, carrying with them an equivalent loss of base cations (K, Ca, and Mg) from the soil. Over prolonged periods, this leaching has negative consequences for the supporting service of soil fertility. Soil acidification can also lead to mobilization of inorganic Al (Reuss 1983) with detrimental effects on tree health, including aluminum interference with calcium uptake, cold tolerance, and aluminum toxicity to roots (Parker et al. 1989; Cronan and Grigal 1995). Low *p*H and inorganic monomeric Al are directly harmful to fish (Baker and Schofield 1982), and fishless lakes in the Adirondacks have significantly lower *p*H and ANC than lakes with fish (Gallagher and Baker 1990). Leaching of Al from soils into sensitive aquatic systems has also been shown to reduce fish diversity (Nierzwicki-Bauer et al. 2010). These acidity-driven shifts in fish abundance and diversity have implications for sport fishing and recreation, as well as cultural and nonuse values, such as use of religious sites or just the knowledge that these native ecosystems exist without human disturbance.

High rates of N loading to surface waters, through saturation of the ecosystem's ability to retain nitrogen (Aber et al. 1989) can contribute to excessive productivity, or eutrophication, characterized by algal blooms that prevent swimming, fish consumption and/or other human use (Van Dolah 2000), hypoxia (Breitburg et al. 2009), shifts in species composition (Vaas and Jordan 1990) and food webs, and water with unpleasant tastes and odors (Pretty et al. 2003). These factors negatively affect fish production, biodiversity, water quality, recreation potential, esthetics, and human health. Dodds et al. (2009) conservatively estimate that the costs of freshwater eutrophication, including costs to recreation, waterfront real estate, and spending on recovery of threatened and endangered species in the United States, are approximately $2.2 billion per year.

Nitrogen can also influence human experiences in nature, which are economically and socially important. Nitrogen is a component of regional haze, which can affect visibility and decrease esthetic enjoyment of places where people live, work, and recreate, including parks and other rural areas (Malm 1989). Visibility damages associated with reactive N in the Chesapeake Bay watershed were $120 million (Birch et al. 2011). Damage costs of HABs to recreation and tourism ranged from <$1 to $28 million (Hoagland et al. 2002). Damages by reactive N to recreational use within the Chesapeake Bay estuary were estimated to be $730 million per year (Birch et al. 2011). Other studies have estimated the value of improving the quality of natural resources by asking people what they are willing to pay. Banzhaf et al. (2006) estimated that New York state residents are willing to pay $45–100 each year to reduce the number of acidified lakes and improve forest health in the Adirondacks, which translates to $300–700 million for all state residents. These traditionally considered 'nonuse values' are an important component to human well-being and thus represent an important and increasingly well-quantified ecosystem service.

4.03.3.4 Climate Regulation

Nitrogen plays a key role in the maintenance of the climate system as a crucial regulating ecosystem service by influencing the production of several greenhouse gases (N_2O, CO_2, and CH_4) through its role as a mediator of aerosol production and due to its influence on biogeochemical processes. Human alteration of the N cycle affects the Earth's climate system via direct and indirect pathways. Nitrogen availability provides

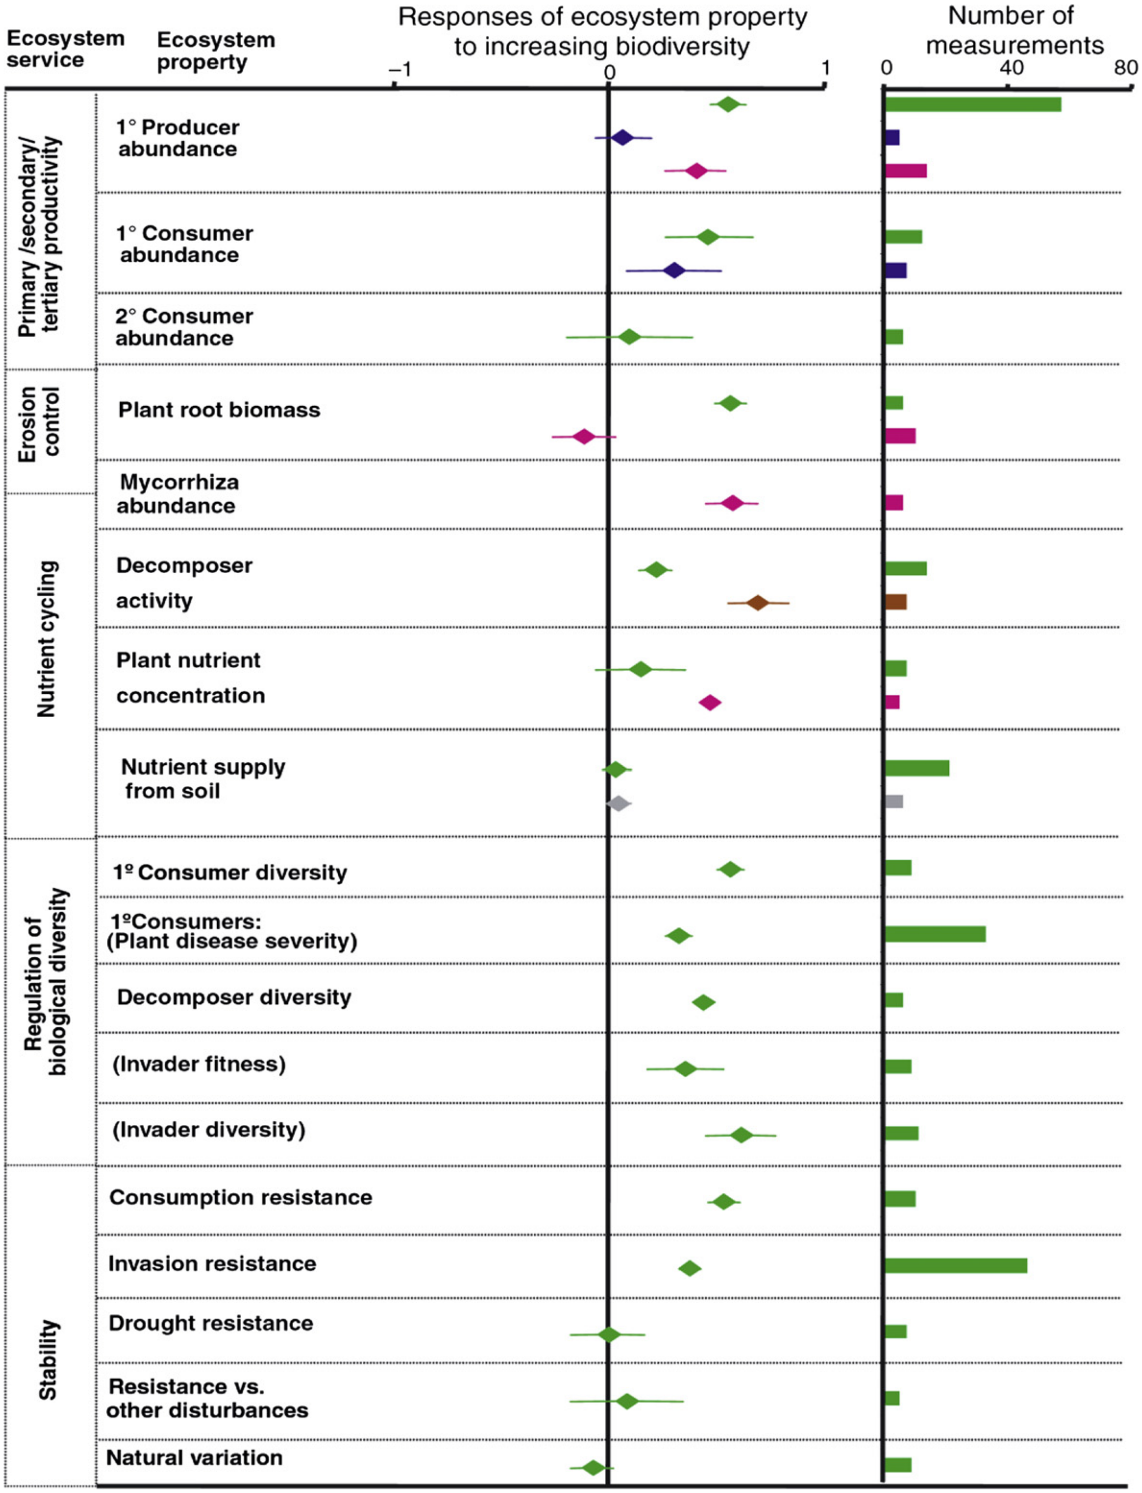

Figure 5 Meta-analysis of the magnitude and direction of biodiversity effects on ecosystem services. Shown are mean values and SE of normalized effect sizes and number of measurements available for ecosystem properties organized into ecosystem services. Colored bars show differential effects of trophic level manipulated: green, primary producers; blue, primary consumers; pink, mycorrhiza; brown, decomposer; gray, multiple trophic levels. Ecosystem properties shown in parentheses were considered of negative value for human well-being, and thus opposite of effect sizes are shown. From Balvanera, P., A. B. Pfisterer, N. Buchmann, J.-S. He, T. Nakashizuka, D. Raffaelli, and B. Schmid, 2006: Quantifying the evidence for biodiversity effects on ecosystem functioning and services. *Ecol. Lett.*, **9,** 1146–1156.

a fundamental constraint on plant growth and net CO_2 uptake across much of the world now and on response to rising atmosphere CO_2 concentrations in the future (Hungate et al. 2003). As discussed above, N inputs from atmospheric deposition can enhance plant growth rates and may account for a significant fraction of current terrestrial C uptake in some systems (Liu and Greaver 2009; Thomas et al. 2010). Furthermore, additions of N to some soils can inhibit decomposition, slowing release of CO_2 to the atmosphere, and leading to an increase in soil C stocks (e.g., Janssens and Luyssaert 2009).

However, net greenhouse benefits of C storage by some ecosystems may be somewhat dampened by the production of other greenhouse gases. In a meta-analysis, nitrogen additions were found to stimulate CH_4 production, decrease CH_4 uptake, and increase N_2O production (Liu and Greaver 2009). Atmospheric N_2O concentrations are rapidly increasing in response to N enrichment of terrestrial and aquatic systems and are presently 16% greater than during preindustrial times (Forster et al. 2007). Kusiima et al. (2010) identify several efforts to provide preliminary values of the anticipated impacts of greenhouse gases of approximately \$4–10 per ton of CO_2, equivalent to \$1.2–3.1 per kg N.

Nitrogen also influences the climate system through its link to ozone. In the lower atmosphere, N plays a key role in tropospheric ozone production (Skalska et al. 2010). In turn, ozone directly affects the climate system by acting as a greenhouse gas with roughly double the climate effect of N_2O (Forster et al. 2007), and indirectly through effects on photosynthesis and plant uptake of atmospheric CO_2. Ozone damage to plants, as discussed earlier in the section on production, may also decrease plant uptake of atmospheric CO_2 by as much as 14–23% (Sitch et al. 2007), leading to more CO_2-driven warming.

In addition to affecting the balance of greenhouse gases in the atmosphere, production of NO_x and NH_x increases the concentrations of atmospheric aerosols, which aside from their negative health effects can provide substantial cooling, both directly (due to high reflectivity) and indirectly (by mediating cloud formation). The influence of reactive N continues into the upper atmosphere, where ozone acts to provide a small amount of cooling. Current efforts are attempting to quantify the net impact of warming and cooling effects relative to reactive nitrogen (Davidson et al. 2012).

4.03.4 Current and Future Trends in N Deposition and Effects on Ecosystem Services: Recovery and Future Research Needs

Release of nitrogen to the atmosphere in the United States has substantially declined during the last few decades (Figure 6), and some of these changes will yield improvements in ecosystem services. The recovery might be most pronounced for those services that are quick to respond, such as those directly derived from the provision of clean air. For example, the 1990 Clean Air Act Amendments and subsequent programs have led to decreases in emissions of NO_x down by 67% in 2009 from 1995 levels. In the United States, these declines have meant less fine particles and ozone in the air, and in turn fewer deaths and hospital visits at an estimated benefit of \$170–430 billion per year (2008 dollars; Burns et al. 2011).

In areas of the northeastern United States where N deposition has declined, there has been a trend toward recovery of surface water chemistry reflected by increases in *p*H and acid neutralizing capacity and decreases in sulfate and to a lesser extent nitrate concentrations (Kahl et al. 2004; Driscoll et al. 2007). Other services may require longer time courses for recovery depending upon the mechanisms involved. Burns et al. (2011) suggest that changes in aquatic biology and terrestrial ecosystem recovery, while expected, have not been well documented since the reductions in N deposition. The loss of biodiversity can occur through a number of different mechanisms, but the driving mechanism was the accumulation and enrichment of ecosystems with N (Bobbink et al. 2010). Recovery was very slow after cessation of N inputs in a long-term grassland experiment, even with only small amounts of increases in N (Clark et al. 2009). Therefore, even though N deposition may have declined, recovery of biodiversity and other important components of ecosystem structure and function may lag behind if the driving mechanisms recover slowly.

4.03.5 Continued Science Needs in Understanding the Impacts of N Deposition on Ecosystem Services

The relative damage costs to different ecosystem services caused by nitrogen are shown in Figure 7. The most costly impacts relate to human health and also to recreation. However, there are many gaps in this analysis, most notably those associated with freshwater ecosystem services, including recreation and harmful algal blooms. Carpenter et al. (2009) call for improved monitoring of ecosystem services, which requires '(i) time series information on land cover and land use, (ii) locations and rates of desertification, (iii) spatial patterns and changes in freshwater quality, (iv) stocks, flows, and economic values of ecosystem services, (v) trends in human use of ecosystem services, and (vi) trends in components of human well-being (particularly those not traditionally measured).' These monitoring needs also apply to our understanding of N deposition effects. Since the benefits to people are best reflected by recreation and nonuse values, there is a need for more data and models linking deposition and these ecosystem services, in addition to the linked water quality indicators that are better studied. In addition, more intermediate connections, such as aquatic biota and terrestrial ecosystem recovery, including biodiversity and forest products, should be examined.

The analysis by Birch et al. (2011) serves as a model approach because it ties the approaches for to reductions to the benefits. They illustrate that the choice of intervention used to achieve N reduction has distinct consequences for ecosystem services and benefits to people. When considering N loading to the Chesapeake Bay watershed, N deposition is not the largest source. Yet, the currently available damage costs associated with atmospheric N emissions are much greater than the other measured costs, primarily due to the high value placed on damages to human health associated with particulate matter and ozone, that is, mortality and hospital visits due to respiratory illness. Air deposition effects were greatest in this analysis, in part because the cost data are available. Future efforts to connect science and policy should attempt to include other

Figure 6 Changes in nitrate (a) and ammonium (b) concentrations in precipitation from 1985 to 2002. Current levels still exceed preindustrial levels in many areas. Reproduced from Lehmann, C. M. B., V. C. Bowersox, and S. M. Larson, 2005: Spatial and temporal trends of precipitation chemistry in the United States,1985–2002. *Environ. Pollut.*, **135,** 347–361.

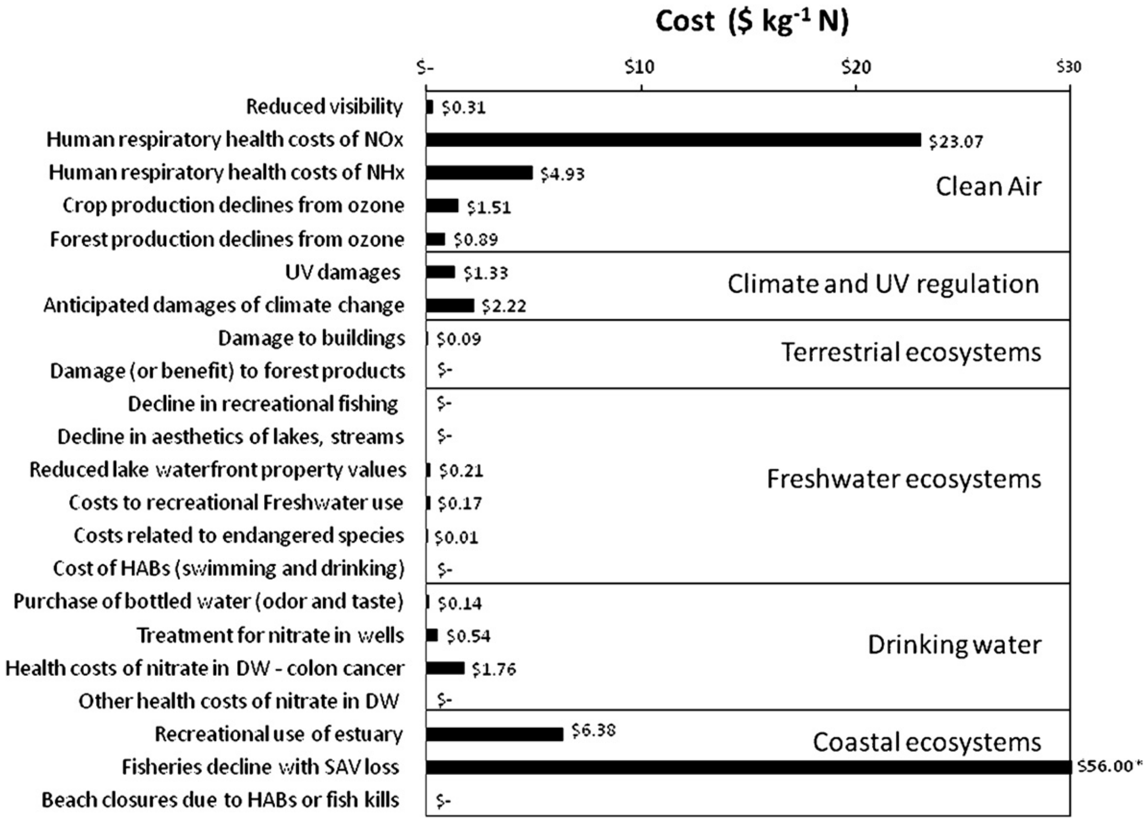

Figure 7 Range of damage cost estimates associated with nitrogen pollution. *One estimate of the cost of damages to coastal fish populations exceeded the scale of the graph. Based on Compton, J. E., J. A. Harrison, R. L. Dennis, T. L. Greaver, B. H. Hill, S. J. Jordan, H. Walker, and H. V. Campbell, 2011: Ecosystem services altered by human changes in the nitrogen cycle: a new perspective for US decision making. *Ecol. Lett.*, **14,** 804–815.

costs, for example, those associated with ozone-depletion, climate change, and freshwater costs, which are gaps in Figure 7. Quantification of ecosystem service impacts tied to the source can help decision-makers evaluate how to prioritize different interventions in the nitrogen cycle to move toward more efficient and sustainable N use.

Acknowledgments

This work was funded by the US Environmental Protection Agency. It has been subject to Agency review and approved for publication. The authors thank Tara Greaver, John Harrison, Paul Ringold, Henry Walker, and Holly Campbell for early discussions of this work. We thank William Currie for extremely helpful comments and for his review of the paper.

Glossary

Biogeochemical Of or relating to the transfer and cycling of energy and materials among the living and nonliving components of ecosystems (such as organisms, soils, bodies of water, and the atmosphere).

Herbivore An animal that feeds on plants.

Herbivory The feeding of an animal on plants.

Legume A plant of the botanical family *Fabaceae*. Many legume species develop symbiotic relationships with bacteria that can fix (acquire) atmospheric nitrogen and make it available for incorporation into organic molecules.

Monoculture An ecological community in which all individuals are members of the same species.

Nonstructural carbohydrate A carbohydrate (starches and sugars) that does not comprise a component of plant cell wall structures. The term is used in comparison with structural carbohydrates, such as cellulose, which make up a large fraction of plant cell walls.

Stomata Small pores on the surfaces of plant leaves through which gases such as carbon dioxide and water vapor are exchanged between plant tissues and the external atmosphere.

Stomatal conductance A measure of the ability of a leaf surface to allow transfer of gases in and out through the stomata. This is closely related to the extent to which the stomata are open at a given moment.

Transpiration The movement of water vapor from a plant into the atmosphere. Takes place largely through stomata.

4.04.1 Introduction

4.04.1.1 Increases in Atmospheric CO_2

Concentrations of carbon dioxide in Earth's atmosphere have been steadily increasing, from an average of approximately 280 ppm (parts per million) prior to the Industrial Revolution (Gerhart and Ward 2010), to approximately 315 ppm in 1959, to a current (2012) average of approximately 392 ppm (Conway and Tans 2012). Projections of concentrations for the year 2100 vary widely, but are mostly in the range of 500–1000 ppm (Solomon et al. 2007). These increases in atmospheric CO_2 concentrations have received a great deal of attention as a potential influence on climate. However, increasing atmospheric concentrations of CO_2 also directly affect biogeochemical processes that directly involve the carbon dioxide molecule including (1) effects on organisms that uptake CO_2 in photosynthesis, (2) decreasing ocean pH due to increased dissolution of CO_2 to form carbonic acid, (3) alterations in oceanic carbonate chemistry, with impacts on marine organisms with calcified body parts. In this review we will focus on direct CO_2 effects on terrestrial plants. We refer readers to Denman et al. (2011), Fabry et al. (2008), and Guniotte and Fabry (2008) for reviews of the effects of rising atmospheric CO_2 on ocean chemistry and marine organisms.

In this review, we first discuss the experimental methodology that has been used to discover the effects of growth under elevated concentrations of CO_2 on plants and plant communities. We then consider the various ways that increased atmospheric concentrations of CO_2 can affect plant growth, chemistry, and physiological functioning, and examine the impact of CO_2 enrichment on plant community structure and function. Finally, we examine ways that the effects of elevated CO_2 on plants may negatively impact the ecosystem services that plants provide. Throughout, it should be noted that we are concerned with the direct effects of increasing atmospheric CO_2 on plants rather than effects that may occur indirectly through the influence of rising atmospheric CO_2 on other aspects of the climate system.

4.04.1.2 Experimental Methodology of Elevated CO_2 Research

Our knowledge of the effects on plants of increased concentrations of atmospheric CO_2 comes from experiments in which plants have been artificially exposed to the CO_2 concentrations anticipated to occur over the next century (aka elevated CO_2 conditions). A wide range of facilities have been used to fumigate plants with elevated CO_2 in this manner. These facilities can be divided into three broad categories.

1. Closed facilities. These facilities include growth chambers, CO_2-controlled greenhouses, and other indoor facilities. Closed facilities have been used widely, and were the earliest technology used for CO_2 enrichment studies. One major advantage of these facilities is the ability to precisely control environmental conditions, including CO_2 concentration, temperature, light intensity, photoperiod, and relative humidity. Another advantage is a relatively low cost of operation. The chief drawback of these facilities is a lack of realism: plants are typically rooted in soil in pots that restrict root growth and environmental conditions inside these facilities can be quite different from field conditions.
2. Semi-open systems. This category is best represented by open-top chambers (OTC). These can be placed in natural and agricultural field settings. Plants in these experiments are often rooted naturally in the soil, and because the chambers have open tops, the environment is much closer to field conditions than inside enclosed facilities. However, plants grown in OTCs usually experience warmer, more humid conditions and lower light intensity than those grown outside (Kimball et al. 1997).
3. Free-air CO_2 enrichment (FACE). In FACE facilities, gas emitters are used to fumigate vegetation with gases such as CO_2 and ozone without enclosing chambers of any kind. FACE can therefore simulate changes in atmospheric composition under realistic field conditions. Because FACE rings are typically larger in size (up to 15–25 m diameter) than either enclosed facilities or OTCs, FACE facilities can also incorporate a large number of plants, and can be used to study ecosystem interactions that occur over somewhat larger spatial scales than for other methods of CO_2 enrichment. The shortcomings of FACE include a high cost of setup and maintenance, and problems maintaining steady CO_2 levels under windy conditions. All things considered, FACE offers the most realistic simulation of the real-world environmental conditions of the future. The first generation of FACE experiments have largely been completed, and researchers have recently been considering ambitious plans for new types of FACE experiments that could operate at even larger scales and with enhanced realism (Ainsworth et al. 2008; Calfapietra et al. 2009). In this article, we incorporate results from all types of CO_2-enrichment facilities, focusing on results from FACE experiments when available. Throughout, we identify the type of research facility from which particular results have been obtained, so the data can be interpreted in the proper context. If we do not specify a particular type of facility, we (or the previous authors we cite) are discussing results drawn from all types of facilities.

4.04.2 Effects of Elevated CO_2 on Plants

4.04.2.1 Physiological Effects

Plants assimilate carbon dioxide through the process of photosynthesis, chemically reducing the carbon to form organic molecules. These organic molecules make up more than 95% of the dry mass of a typical plant and provide energy for the plant's metabolism. Because CO_2 plays this pivotal role in plant metabolism, rising atmospheric CO_2 concentrations can be expected to alter a great many aspects of plant physiology and chemistry.

4.04.2.1.1 Photosynthesis and Growth

Plants grown under elevated CO_2 conditions typically experience increased rates of photosynthetic carbon fixation. Reviewing FACE studies performed on a broad range of plant species, Ainsworth and Rogers (2007) found an average increase in photosynthetic rates under elevated CO_2 (475–600 ppm) of 40%. The increased availability of reduced carbon compounds such as carbohydrates provided by this increased photosynthesis increases the growth rate for most plants. In FACE experiments, elevated CO_2 increased dry matter production of above-ground tissues by an average of 17% and production of below-ground tissues by more than 30% (Ainsworth and Long 2005; de Graaff et al. 2006). Norby and Zak (2011) found an average stimulation of net primary productivity (roughly defined as the amount of organic biomass entering an ecosystem through the photosynthetic organisms living there) of 23% in FACE experiments in forest ecosystems. Crop yields are also increased under elevated CO_2. Yields of wheat, rice, barley, and soybean increase by an average of 12–17% in FACE experiments (Ainsworth 2008; Ainsworth and McGrath 2010; Long et al. 2006). Yields of potato tubers increase even more, by ~30% on average (Ainsworth and McGrath 2010; Kimball 2010).

4.04.2.1.2 Transpiration and Water Use

Atmospheric concentrations of CO_2 can also affect plant water use. Carbon dioxide concentrations play a central role in controlling the aperture of stomata, small pores on the surfaces of plants, particularly on the underside of leaves. Open stomata provide a pathway for CO_2 to diffuse into leaves for photosynthesis, but also a pathway for water to diffuse out from leaves. Stomatal aperture (closely related to a physiological measure known as stomatal conductance) is therefore regulated to balance the goals of maintaining CO_2 assimilation and minimizing water loss. At higher concentrations of atmospheric CO_2, plants are able to achieve high rates of photosynthesis with relatively low stomatal conductance. In FACE experiments, elevated CO_2 decreases stomatal conductance by an average of 22% (Ainsworth and Rogers 2007).

Effects of elevated CO_2 on water use by whole plants or plant communities will depend not only on effects on stomatal conductance and leaf-level transpiration, but also on other potential effects of elevated CO_2, such as changes in plant size and morphology. For example, increased growth of plants may lead to increased numbers of leaves, offsetting decreased transpiration per leaf (Warren et al. 2011). Nonetheless, the overall effect of elevated CO_2 appears to be a decrease in total plant and ecosystem water usage, by approximately 5–20% in FACE experiments (Kimball 2010; Leakey et al. 2009). This can lead to alterations of ecosystem hydrology, including an increase in soil moisture and perhaps runoff (Leakey et al. 2009; Norby and Zak 2011).

4.04.2.1.3 Plant Chemical Composition

Growth of plants under elevated CO_2 conditions can affect the chemistry of plants in a number of ways. In FACE experiments, enhanced photosynthetic activity under elevated CO_2 leads to an increase, on average, of 30–40% in leaf nonstructural carbohydrates per unit leaf area (Ainsworth 2008; Ainsworth and Long 2005). Tissue concentrations of nitrogen (N), in contrast, typically decrease under elevated CO_2 (Cotrufo et al. 1998). Surveys of the research literature have found decreases in N concentrations averaging approximately 10–15% for leaves of woody plants (Curtis and Wang 1998; Norby et al. 1999), for leaves of all species under FACE conditions (Ainsworth and Long 2005), seeds (Jablonski et al. 2002), and stems and roots (Cotrufo et al. 1998).

Although the various literature surveys have found similar mean effects of elevated CO_2, effects in individual experiments vary in magnitude. In one survey, Norby et al. (1999) found that changes in leaf N concentration in leaves ranged from a decrease of 35% to an increase of 20%. Yin (2002) found an even greater range in the studies he reviewed from a 56% decrease to a 20% increase in leaf N.

The decreased concentrations of nitrogen typically observed under elevated CO_2 conditions appear to be, at least in part, directly tied to the increased plant concentrations of carbohydrates (Taub and Wang 2008). Carbohydrates are composed largely of carbon, hydrogen, and oxygen. Increasing concentrations of carbohydrates therefore increases the proportion of plant mass composed of these elements, while decreasing the proportion accounted for by other elements such as nitrogen.

Increased concentrations of nonstructural carbohydrates cannot fully account for the observed effects of elevated CO_2 on plant nitrogen. Poorter et al. (1997), in experiments with 27 plant species, found that growth at elevated CO_2 decreased leaf nitrogen concentrations by an average of 17%. When they recalculated after subtracting out nonstructural carbohydrates, the effect of elevated CO_2 was diminished, but there was a still-significant 10% decrease in N concentrations. Taub and Wang (2008) similarly found that, in various studies, 'dilution' by increased concentrations of carbohydrates could account for only a portion of the decrease in N under elevated CO_2.

In addition to carbohydrate dilution, a number of alternative physiological mechanisms have been suggested to contribute to the decreases in N concentrations (reviewed by Taub and Wang 2008, 2011). Of these, perhaps the best supported explanation is a decrease in transpirationally mediated N uptake. Water flowing through soil to plant roots carries dissolved minerals with it. Decreasing plant uptake of water caused by decreased stomatal conductance under elevated CO_2 can therefore potentially decrease uptake of mineral elements such as nitrogen (McDonald et al. 2002).

Although the effect of elevated CO_2 on mineral element concentrations has been best studied for nitrogen, it appears that plant concentrations of other minerals may also be decreased under elevated CO_2. Loladze (2002) suggested that plant concentrations of all elements other than carbon, hydrogen, and oxygen should be decreased under elevated CO_2. He also presented data suggesting that this was indeed the case for most mineral elements in both leaves and in wheat grains. The mechanism(s) responsible for decreasing concentrations of these elements may be similar to those for nitrogen. Dilution through carbohydrate accumulation would be expected to equally impact all elements except for C, H, and O (the elements that carbohydrates are composed of), and decreased uptake through decreased transpirational flow of water would be expected to impact all elements obtained through the soil, though to a degree that would differ depending on properties affecting the interactions of particular mineral ions with soils.

4.04.2.2 Effects of Other Environmental Factors on Plant Responses to Elevated CO_2

In the foregoing discussion, we have focused on the average effects of CO_2 enrichment on growth and physiology of plants across all types of environmental conditions. However, the effects of elevated CO_2 on plants interact with those of other environmental factors, most notably soil water, soil fertility, air temperature, and ozone pollution.

4.04.2.2.1 Soil Water

Water availability is of primary importance to plant growth and affects growth responses to elevated CO_2 (Curtis and Wang 1998; Idso and Idso 1994; Körner 2003; Poorter and Perez-Soba 2001; Wullschleger et al. 2002). Plants do not grow well when water is limited, regardless of CO_2 concentration. However, CO_2 enrichment is able to alleviate the negative effect of drought stress on plant growth because plants can close their stomata (small openings on leaf surface) and still let in sufficient CO_2 for photosynthesis. In addition, plants grown under water stress allocate more biomass belowground and develop more extensive root systems (Curtis et al. 1990; Idso et al. 1988; Wang and Taub 2010). As a result, the relative responsiveness to elevated CO_2 in biomass production is typically higher in drier soil than under well-watered conditions, although the absolute biomass production will be lower (Idso and Idso 1994).

4.04.2.2.2 Soil Fertility

Although elevated CO_2 makes carbon more abundant and available for photosynthesis, plants require other resources to fully take advantage of this additional carbon, including a variety of minerals obtained from the soil. Not only does elevated CO_2 not make these soil-derived mineral elements more available, it may even decrease their uptake under certain conditions (see Section 2.01.3 Vulnerabilities; Taub and Wang 2008). Under conditions of low soil fertility, plants may therefore experience diminished ability to increase photosynthesis and growth in response to elevated CO_2. This effect has been particularly noted for nitrogen. Photosynthesis and crop yield are enhanced by elevated CO_2 less under low soil N condition than under high soil N in FACE experiments (Ainsworth 2008; Ainsworth and Long 2005; Ainsworth and Rogers 2007; Long et al. 2006). Biomass production is enhanced by elevated CO_2 less under low nutrient conditions than high nutrient conditions across studies using all types of CO_2 enrichment technology (Idso and Idso 1994; Poorter and Navas 2003).

4.04.2.2.3 Air Temperature

Temperature records in many localities of the world have shown warming trends and rising CO_2 concentrations in the atmosphere have the potential to enhance these trends (Solomon et al. 2007). Within a certain temperature range, increases in temperature increase the photosynthetic rate of green plants (Farquhar et al. 1980). The photosynthetic temperature optimum, the temperature at which photosynthesis is maximal, generally increases with rising CO_2 level (Berry and Bjorkman 1980; Long 1991; McMurtrie and Wang 1993). Higher temperatures therefore tend to amplify the enhancing effect of CO_2 enrichment on plant growth.

4.04.2.2.4 Ozone Pollution

Ozone gas (O_3) exists both in earth's upper atmosphere (where it is vital to our well-being due to its absorption of ultraviolent radiation) and at ground level where it is largely a toxic by-product of air pollution. Ground-level concentrations of O_3 worldwide are steadily increasing due to increased emissions of chemicals that react to produce ozone (Vingarzan 2004). Ozone at high concentrations causes damage to the internal tissues of leaves, leading to decreased photosynthesis and growth (Feng et al. 2008; Morgan et al. 2003). However, plants grown under elevated CO_2 typically decrease openness of stomata (see Section 2.01.2; Curtis and Wang 1998; Medlyn et al. 2001) and can therefore decrease exposure of internal leaf tissues to O_3. Enhancement of plant growth by elevated CO_2 is typically much greater when plants are stressed by high O_3 concentrations than otherwise (Poorter and Navas 2003). Growth under elevated CO_2 has also been shown to decrease the negative effects of high O_3 on photosynthesis, growth, and seed production in several crop species (Feng et al. 2008; Morgan et al. 2003). There is also evidence that elevated levels of CO_2 and O_3 interact in affecting plant biomass allocation. Wang and Taub (2010) found that plants grown under elevated CO_2 and elevated O_3 increased allocation of biomass belowground compared to those grown under ambient conditions. This altered allocation of biomass at elevated O_3 may have important implications for the global carbon cycle because biomass below-ground differs greatly from biomass aboveground in terms of the length of time carbon is sequestered away from the atmosphere.

4.04.2.3 Differences among Plants in Responses to Elevated CO_2

4.04.2.3.1 Variation in Photosynthetic Processes and Responses to Elevated CO_2

Previously, we have discussed the average effects of growth under elevated CO_2 across all species of plants. However there are important differences in response to CO_2 among different types of plants. Perhaps the two most important determinants of plant species' responses to elevated CO_2 are (1) the variant of photosynthetic physiology that a species uses and (2) whether the species is a legume.

There are several major variants of photosynthetic physiology found in land plants. The great majority of plant species (~90%) use the photosynthetic mechanism known as C_3 photosynthesis. The other photosynthetic variants, known as CAM and C_4 photosynthesis, have evolved as elaborations from C_3 photosynthesis. Although a greater number of species use CAM than C_4 photosynthesis, C_4 plants are probably of greater ecological importance, as this type of physiology is found in the majority of grass species that are the dominant vegetation throughout tropical and subtropical grasslands and savannahs (Sage et al. 1999). Additionally, while there is only one CAM species of major agronomic importance (pineapple), the C_4 mechanism is used by a number of important crop species, including maize, sorghum, sugar cane, and the various millet species. Corresponding with these differences in ecological and economic importance, there has been considerably more research performed on responses to elevated CO_2 for C_4 species than for CAM species.

Plants that utilize the C_4 variant of photosynthesis biochemically concentrate CO_2 in specialized bundle sheath cells within the leaf. For C_4 species, it is within these cells that the incorporation of CO_2 into organic compounds by the Calvin photosynthetic cycle takes place. Because the plants already concentrate CO_2 within the bundle sheath cells, C_4 species experience little increase in photosynthetic rates from increasing atmospheric CO_2 concentrations above the current ambient. Stomatal conductance does decrease under elevated CO_2, much as with C_3 species. Under conditions of drought this may alleviate some of the effects of water stress, indirectly leading to higher photosynthetic rates and increased growth under elevated than ambient CO_2 conditions (Kimball 2010; Leakey et al. 2009). Overall, in FACE experiments, C_4 plants show approximately one-third of the increase of photosynthetic rates experienced by C_3 species, and little enhancement of growth (Ainsworth and Long 2005). There also appears to be little or no increase in grain yields for C_4 crops under elevated CO_2 in FACE studies (Ainsworth and McGrath 2010; Long et al. 2006). C_4 plants also show much less of a response of nitrogen and protein concentrations to elevated CO_2 than do C_3 plants (Cotrufo et al. 1998). In most respects, therefore, C_4 plants can be expected to be less responsive than C_3 plants to increasing atmospheric CO_2.

4.04.2.3.2 Responses to Elevated CO_2 in Legumes

In contrast to the relative unresponsiveness of C_4 species to elevated atmospheric CO_2, legumes (plants of the botanical family *Fabaceae*; all perform C_3 photosynthesis) respond particularly strongly with increased photosynthesis and growth (Rogers et al. 2009). As we have discussed, for most plants elevated CO_2 alters the balance between internal concentrations of carbon and nitrogen. Legumes, however, form symbiotic relationships with bacteria that live in nodules on the plant's roots. These bacteria are capable of a process known as nitrogen fixation, in which atmospheric nitrogen is chemically reduced to a form in which it can enter into metabolism by the bacterium or plant and become incorporated into molecules such as proteins and nucleic acids. When grown under elevated CO_2, legumes may be able to direct carbohydrates obtained through enhanced photosynthesis to the root nodules. There the carbohydrates can provide a carbon and energy source for the nitrogen-fixing bacteria. When other nutrients are not limiting, legumes often experience increases in fixation of nitrogen by their bacterial symbionts under elevated CO_2 (de Graaff et al. 2006; Lee et al. 2003; Rogers et al. 2009; Schortemeyer et al. 2002; Zanetti et al. 1996). Being able to exchange carbon for nitrogen in this way may enable legumes to maximize the beneficial effects of elevated CO_2, and obtain greater enhancement of photosynthesis and growth than shown by most other plant species (Rogers et al. 2009). In addition, the greater availability of nitrogen often prevents at least some of the decrease in nitrogen concentrations seen in other plants grown under elevated CO_2. Cotrufo et al. (1998) reviewing evidence from a large range of studies found an average decrease in tissue nitrogen concentrations in legumes of 7%, compared to 16% for C_3 plant species lacking N-fixing symbionts. Jablonski et al. (2002) found no decrease in nitrogen concentrations under elevated CO_2 in the seeds of legumes, compared to an average decrease of 14% in the seeds of nonlegume C_3 plants.

4.04.2.3.3 CO_2 Responses in Crops versus Wild Species

Populations of wild and crop species provide additional insight on the responsiveness of plant growth under CO_2 enrichment in different plants. Wild and crop species are different in many ways, particularly in the traits that have been subject to intensive selection by humans. As a result, wild and crop species respond differently to CO_2 enrichment in growth and reproduction (Figure 1). Crops both allocate a larger proportion of biomass to reproduction than wild species and respond more in fruit and seed production than wild species to CO_2 enrichment (Jablonski et al. 2002). Biomass production is enhanced to a greater extent in crops than wild species

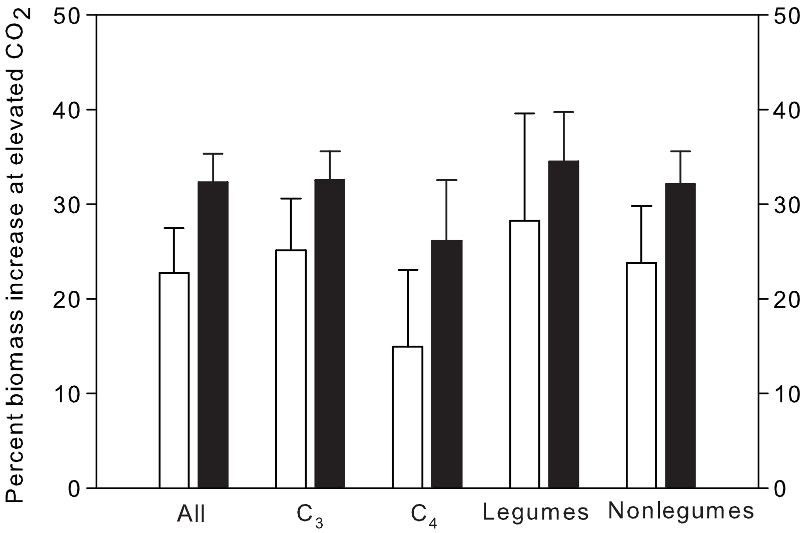

Figure 1 Percent increase in total biomass production of herbaceous wild (unfilled bars) and crop (filled bars) species grown at elevated CO_2. Mean ± 95% confidence interval. For better comparison, only nonlegumes that are C_3 species are included in the analysis because all legumes are C_3 species. A number of studies for the response variables for ambient and elevated CO_2 are 186 and 334 (all), 143 and 323 (C_3), 43 and 11 (C_4), 43 and 54 (legumes), and 100 and 269 (nonlegumes).

(Wang et al. 2008), although the magnitude of response differs among plant functional groups (i.e., C_3 vs. C_4 species and legumes vs. nonlegumes; **Figure 1**). It should be noted that the results synthesized in Wang et al. (2008) were from monocultures. The effects of CO_2 enrichment may be different for plants when they are grown in competition with plants of different species.

4.04.2.4 Effects of Elevated CO_2 on Plant Communities

4.04.2.4.1 Responses to Elevated CO_2 in Monocultures versus Mixed-Species Communities

The effect of CO_2 enrichment on plant biomass production has been found to be different among different types of plant communities. For example, monocultures (plant communities composed of individuals of a single species) and mixed-species communities (plant communities composed of individuals of different species) differ in their responsiveness to CO_2 enrichment in terms of biomass accumulation. The magnitude of responsiveness is primarily determined by the responsiveness of the species themselves to CO_2 enrichment and by the ratio of the more to less responsive plant species in the community.

Results from a FACE study on grassland species showed that growth responsiveness to CO_2 enrichment was greater in mixed-species communities than in monocultures, suggesting that greater species richness would increase plant productivity responsiveness to elevated CO_2 (Reich et al. 2001, 2004). One mechanism that was proposed to explain the difference between monocultures and mixed-species communities was niche complementarity, that the use of resources differed among species and therefore allowed more efficient use of limited resources when there are multiple species in a community. A synthesis of a great number of independent studies by multiple researchers using various CO_2 exposure facilities, however, found that effects of elevated CO_2 on plant growth were generally less pronounced in mixed-species communities than in monocultures (Wang 2007). This pattern of greater responsiveness in monocultures was consistent across different growth forms and functional groups of plants, although the magnitude of response was dependent on other environmental factors, particularly soil nitrogen (Wang 2007). Although resource complementarity in mixed-species communities would be expected to increase responsiveness to elevated CO_2, there may be other factors that counteract the positive effects of resource complementarity (Wang 2007). In some mixed-species communities, plant species that are relatively unresponsive to elevated CO_2 may utilize a large share of limited resources, but contribute little to the overall biomass production of the community. If this mechanism, known as resource usurpation, is more dominant than niche complementarity in a community, plant production will respond less to CO_2 enrichment than in a monoculture of a responsive species. Based on a survey of the relevant research literature, this seems to be most generally the case (Wang 2007). Because plants grow in mixed-species communities under most real-world conditions, estimates of the effects of a CO_2 enriched environment on plant productivity derived from the numerous monoculture experiments that have been performed may have been overly optimistic.

4.04.2.4.2 Changes in Species Composition

Plant species not only differ in their responses to elevated CO_2, but also can alter the responsiveness of neighboring species to CO_2 enrichment. In some cases, a species that responds positively to CO_2 enrichment when grown as isolated individual plants or in monoculture will actually show decreased growth under elevated CO_2 in a mixed-species community (Poorter and Navas 2003). This will occur when the direct benefits of the elevated CO_2 are outweighed by increased competition from neighboring species that experience a greater stimulation of growth from the elevated CO_2. Increased atmospheric concentrations of CO_2 may therefore change the species composition of plant communities, as some species benefit more from elevated CO_2 than others. In experiments in mixed-species communities, C_4 plants often decrease as a proportion of total plant biomass under elevated CO_2, probably because the photosynthetic capacity of C_4 plants is saturated at a lower CO_2 concentration than it is for C_3 plants. Conversely, in mixed-species communities, legumes typically increase as a proportion of total biomass under elevated CO_2 (Poorter and Navas 2003). This is a result of legumes' ability to take fuller advantage of the increased CO_2 because their bacterial symbionts can convert atmospheric nitrogen, which cannot be used directly by nonlegumes as a nutrient, into a usable form of nitrogen. Other environmental factors will also interact with CO_2 enrichment in shaping community structure in a higher CO_2 environment, because species differ in their response and tolerance to these other effects, such as drought, elevated ozone, and higher temperature (Ainsworth and Long 2005; Bazzaz and Carlson 1984; Curtis and Wang 1998; de Graaff et al. 2006; Idso and Idso 1994; Kimball 1983). For example, Morgan et al. (2011) in a FACE experiment in a semiarid grassland community found that responses to elevated CO_2 in the biomass of C_3 and C_4 grasses varied among years, depending on the amount of precipitation during the growing season. They also found that C_4, but not C_3, grasses showed a positive biomass response to the combination of elevated CO_2 and experimentally increased temperature.

4.04.3 Potential Threats to Ecosystem Services from Elevated CO_2

4.04.3.1 Introduction

From a human vantage, the effects of increasing atmospheric CO_2 on plants may have both positive and negative influences on ecosystem services. Increases in the harvestable yield of many crops (Ainsworth 2008; Ainsworth and McGrath 2010; Long et al. 2006), for example, may be regarded as a significant benefit of increased CO_2 (note that the direct positive effects of elevated CO_2 on yield may be negated by effects of changes in weather patterns including temperature on crop yields; e.g., Lobell et al. 2011; Schlenker and Roberts 2009). However, in this section we focus on possible threats to ecosystem services from increasing atmospheric CO_2, rather than possible benefits. We do this not to suggest that negative effects predominate, but because these are the effects for which preventative, adaptive, or ameliorative actions may be required.

4.04.3.2 Effects on Human and Animal Nutrition

4.04.3.2.1 Decreases in Protein and Mineral Concentrations in Food Crops

A major concern with decreasing concentrations of nitrogen and other mineral elements in plant tissues is the potential impact on human nutrition. Nitrogen concentrations are particularly important in this regard. The amino acids that proteins are made of incorporate nitrogen in their chemical structures, and availability of nitrogen exerts a control on plant synthesis of proteins. Total nitrogen concentration in plant tissues is therefore closely related to protein concentration; indeed, the most commonly used analytical chemistry methods for measuring protein in crops actually involve measurement of plant nitrogen (e.g., AOAC 1990). The decreased concentrations of nitrogen observed in plants under elevated CO_2 therefore indicate decreased protein concentrations.

Taub et al. (2008) synthesized the experimental evidence on the effects of growth under elevated CO_2 on protein concentrations in the edible portions of major food crops. Decreases averaging approximately 10–15% were seen in the grains of wheat, rice, barley, and in potato tubers. For soybean, a legume, the decrease in seed protein concentration averaged only 1.3%.

This effect of elevated CO_2 on crop protein concentrations can vary with other environmental factors. For wheat, the effect of elevated CO_2 is decreased, but not eliminated, under conditions of high nitrogen fertility (**Figure 2**). Although similar data are not as readily available for other crops, the physiology of plant responses to nitrogen and CO_2 suggest that this should hold true for other nonlegume crops as well. Protein concentrations in potatoes are decreased by CO_2 more under high atmospheric concentrations of ozone (a toxic gas that is also increasing in concentration in the atmosphere near the earth's surface) than under low concentrations (**Figure 2**).

Decreases in grain protein under elevated CO_2 have been seen consistently across experiments that employed a wide range of crops, crop cultivars, environmental conditions, and experimental techniques (**Figure 3**). This suggests that decreasing crop protein concentrations under elevated CO_2 are a robust finding, likely to apply in the real-world elevated CO_2 conditions of the next century. However, because the magnitude of the CO_2 effect varies with environmental factors such as N and ozone and across experiments using different CO_2-enrichment technologies, it is difficult to estimate a precise magnitude for the average decrease in protein concentrations that will be seen under the real-world agricultural conditions of the next century.

The decreases in protein concentrations under elevated CO_2 that have been well-documented for wheat, rice and barley are likely to hold for other C_3 cereal crops, such as rye and oats (**Figure 4**, also Sæbø and Mortensen 1996). Similarly the decreases observed in potato tuber protein may also be found in other root crops (**Figure 4**, also Lu et al. 1986). On the other hand, the limited data on grain protein under elevated CO_2 for C_4 cereals such as maize and the millets shows little, if any,

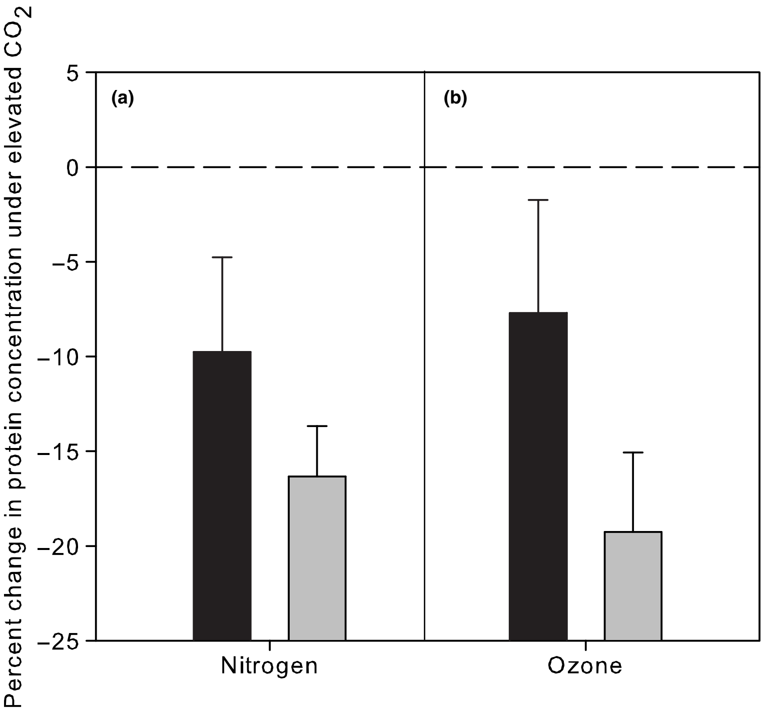

Figure 2 Effects of other environmental factors on the response of crop protein concentrations to elevated CO_2. (a) Effect of nitrogen supply on response of wheat protein concentration to CO_2 ($n = 15$). Dark bars: high N supply, light bars: low N supply. (b) Effect of ozone on response of potato protein concentration to CO_2 ($n = 7$). Dark bars: low atmospheric ozone concentrations, light bars: high atmospheric ozone concentrations. All data are taken from experiments that examined the effect of elevated CO_2 at both high and low N or high and low ozone. Means and 95% confidence intervals. Based on reanalysis of data from Taub, D., B. Miller, and H. Allen, 2008: Effects of elevated CO_2 on the protein concentration of food crops: a meta-analysis. *Glob. Change Biol.*, **14,** 565–575.

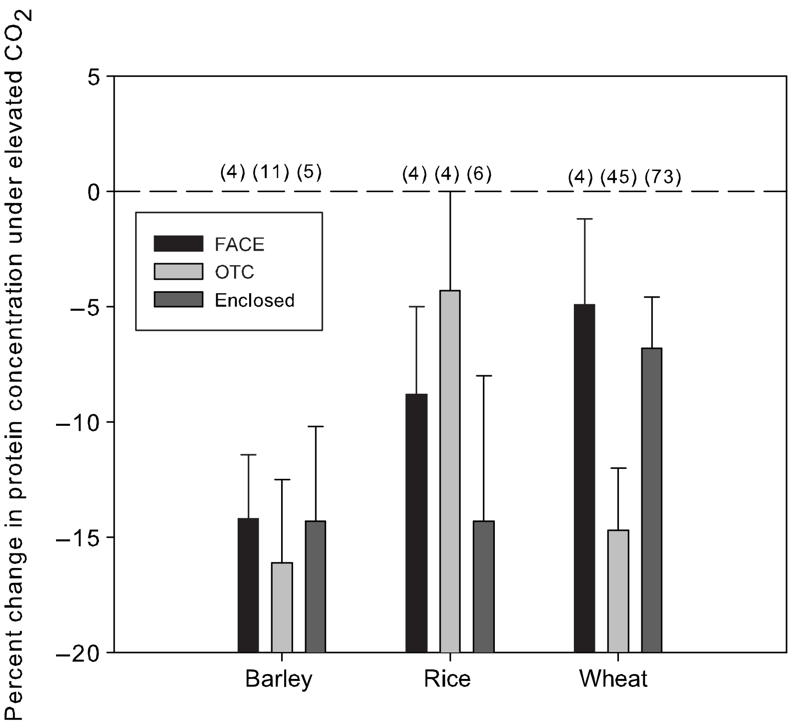

Figure 3 Effect of growth under elevated CO_2 on crop protein concentrations in experiments using different methods of CO_2 fumigation. Means and 95% confidence intervals. Number of experimental observations in parentheses. FACE, free-air carbon dioxide enrichment; OTC, open-top chambers; see text for description of fumigation technologies. Based on reanalysis of data from Taub, D., B. Miller, and H. Allen, 2008: Effects of elevated CO_2 on the protein concentration of food crops: a meta-analysis. *Glob. Change Biol.,* **14,** 565–575.

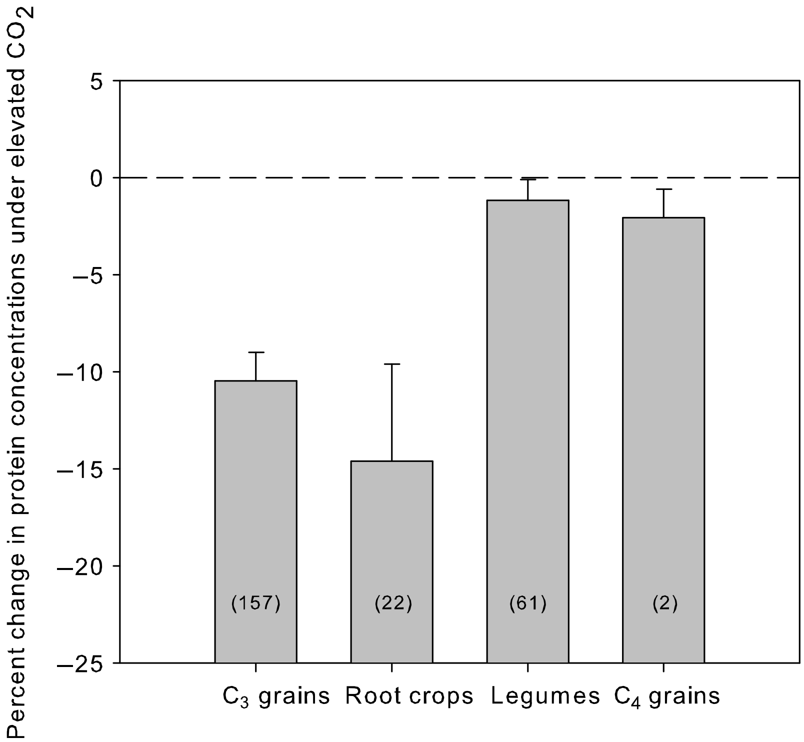

Figure 4 Effect of growth under elevated CO_2 on protein concentrations in several important crop types. Data on C_3 grains include studies on wheat, rice, barley, and oats. Data on root crops include studies on potato, sweet potato, and radish. Data on legumes include studies on soybean, peanut, cowpea, and fava bean. Means and 95% confidence intervals. Number of experimental observations in parentheses. Analysis expands on that of Taub, D., B. Miller, and H. Allen, 2008: Effects of elevated CO_2 on the protein concentration of food crops: a meta-analysis. *Glob. Change Biol.*, **14,** 565–575.

effect on grain protein concentrations (Figure 4; also Rogers et al. 1983). It also appears that the relatively modest effect of elevated CO_2 on protein concentrations in soybean may also hold for other legume crops (Figure 3; also Mbikayi et al. 1988; Rogers et al. 2009; Wolf 1996).

4.04.3.2.2 Effects of Elevated CO_2 on Human Dietary Protein

Human dietary protein is obtained from a variety of sources, including animal products, as well as a variety of plant foods, particularly legumes and grains, and in some cases root crops. Considering that C_3 grains and root crops appear to be particularly affected in protein concentration, we may expect dietary protein intake to be affected by elevated CO_2 to the extent that a particular population relies on these foods as sources of protein.

We have calculated for 173 nations the proportion of total dietary protein (from both plant and animal sources) comprised of C_3 grains and root crops (c.f. Taub and Wang 2011).

Worldwide, nearly 40% of human dietary protein is obtained directly from these types of crops (Table 1). This proportion varies widely among nations, from a low of 4.9% for Burkina Faso to a high of 76.8% for Bangladesh. For 27 nations, mostly in Asia and North Africa, more than half of total dietary protein is derived directly from C_3 grains and root crops. In contrast, for 19 nations, mostly in sub-Saharan Africa and Latin America, less than 20% of total dietary protein is derived from such sources. These appear mostly to be nations with a strong dietary reliance on C_4 grains (maize, sorghum, and the millets).

There are much less data available on the effects of elevated CO_2 for crop mineral concentrations than there for protein. Loladze (2002) lamented the scarcity of such data even for the major staple crops rice and wheat. His synthesis of the limited data available for wheat grains did show average decreases in concentrations of approximately 10–20% for most mineral

Table 1 Contributions of C_3 grains and root crops to total human dietary protein, by nation. These crop types are particularly liable to decreased protein concentrations as atmospheric concentrations of carbon dioxide increase (see text). Total protein includes both plant and animal sources. Nations deriving 50% or more of dietary protein from C_3 grains and root crops are shown in bold. Data calculated from FAO Food Balance sheets for 2003

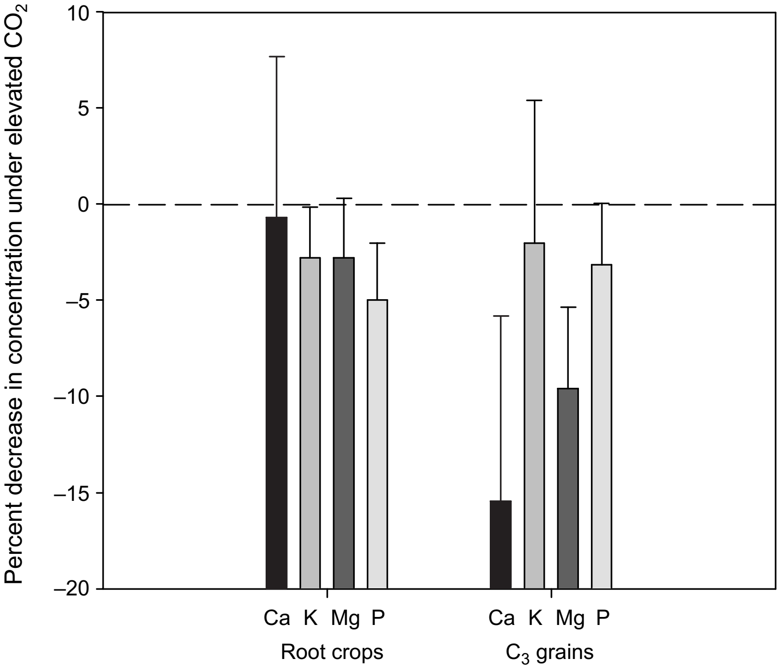

Figure 5 Effect of growth under elevated CO_2 on crop mineral concentrations. Means and 95% confidence intervals. Data taken from studies that measured all four minerals in the same tissues. For root crops, $n = 14$, for C_3 grains, $n = 16$. D.R. Taub and X. Wang, previously unpublished analysis.

elements, including calcium, iron, zinc, magnesium, and manganese, with a smaller decrease for phosphorous. In our own synthesis, there appears to be a general decrease in concentrations of the macronutrient mineral elements (those found in relatively high concentrations in plant tissues), particularly for C_3 grains, but also for root crops, although of a smaller magnitude (Figure 5).

The may be opportunities for mitigation of decreasing crop nutrient concentrations through adjustment of agricultural practices. Idso and Idso (2001) proposed that decreases in crop protein concentrations could be diminished or eliminated through increased use of nitrogen fertilizers. Supporting this, Taub et al. (2008) found that wheat protein concentrations were decreased by elevated CO_2 less under condition of high nitrogen supply (although protein concentrations still did decrease significantly). Adoption of this strategy would of course be difficult or impossible for those farmers with limited access to chemical fertilizers (UN Millennium Project 2005), and populations dependent on food supplied by such farmers may therefore remain particularly vulnerable to decreasing protein content as atmospheric concentrations of carbon dioxide continue to increase.

4.04.3.2.3 Effects of Past Increases in Atmospheric CO_2 on Food Quality

Although we are focused on potential effects of future increases in atmospheric CO_2, it is worth noting that the protein and mineral contents of crops may have already been affected by recent increases in CO_2. Experiments have found lower concentrations of protein in wheat flour from plants grown at current atmospheric CO_2 concentrations than in those grown at the concentrations found prior to the industrial revolution (Rogers et al. 1998; Ziska et al. 2004). Decreasing concentrations of protein have also been reported for wheat harvested in New South Wales, Australia between 1968 and 1990 (Conroy and Hocking 1993) and for a variety of garden crops in the United States from 1950–99 (Davis et al. 2004). Davis et al. (2004) also found decreases of 10–15% over the same time period for Ca, P, and Fe in food crops. Both Conroy and Hocking (1993) and Davis et al. (2004) suggested that changes in the cultivars used in agriculture likely accounted for much of the observed decreases in protein and mineral concentrations, but that increased atmospheric concentrations of CO_2 may also have contributed.

4.04.3.3.4 Effects of Elevated CO_2 on Forage Quality

In addition to decreasing nutrient concentrations in human food crops, increased atmospheric concentrations of CO_2 are likely to decrease protein and mineral concentrations in livestock forage species. For proteins, experiments show decreases in protein concentrations not only for forage grass species, but somewhat surprisingly, even for legume forages (Figure 6). Although there are less data available for minerals (other than N) than for protein, decreased concentrations of such minerals as phosphorus, potassium, and magnesium have been seen in both C_3 and C_4 forage species (Morgan et al. 1994; Newbery et al. 1995; Overdieck 1993; Owensby et al. 1993; Schenk et al. 1997).

The overall effect of elevated CO_2 on forage quality in mixed-species forage will be affected not only by changes in the nutrient content of each plant species, but by any changes that may occur in the species composition of the plant community (see Section 4.04.2.3.3). For example, Polley et al. (2011) in a tall grass prairie observed some decreases in mineral concentrations

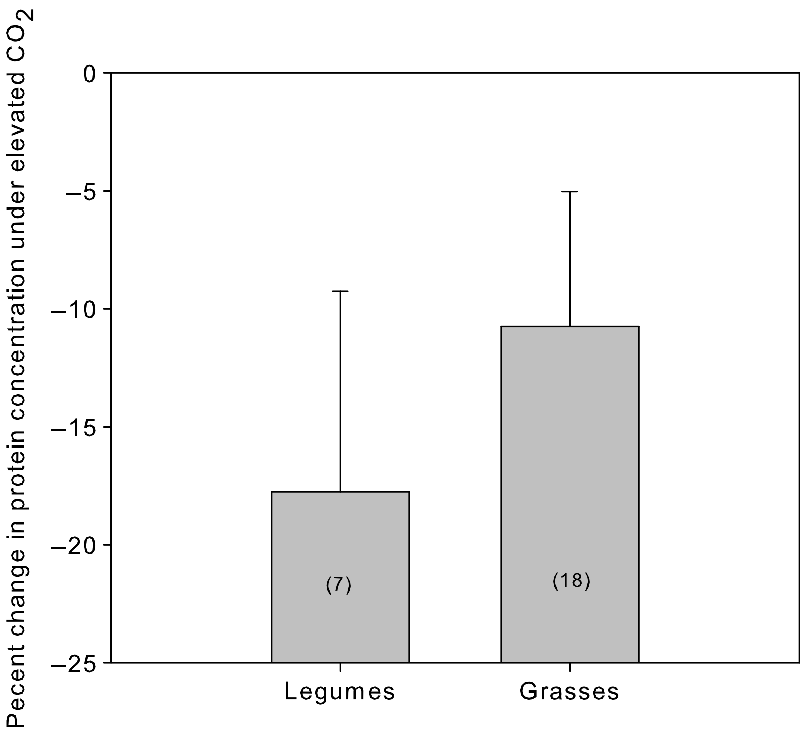

Figure 6 Effect of growth under elevated CO_2 on protein concentrations in legume and grass forage. Means and 95% confidence intervals. Number of experimental observations in parentheses. D.R. Taub and X. Wang, previously unpublished analysis.

(particularly phosphorus) of individual plant species under elevated CO_2. However, this was accompanied by shifts in the plant community toward species with a higher mineral content. The overall effect was therefore an increase in the average mineral concentration of the total available forage. This effect is likely specific to this plant community; in other communities, elevated CO_2 might instead favor plant species with a relatively low mineral content. In this case, changes in the plant community would exacerbate rather than ameliorate the decreases in forage mineral concentrations for individual plant species. On balance, because most forage species can be expected to experience decreased protein and mineral concentrations under elevated CO_2, nutrient concentrations in forage will likely decline, with potentially negative effects on livestock health and growth.

4.04.3.3 Impact on Undesirable Species

Weeds are undoubtedly the most prominent group of undesirable plant species because they infest a large number of agricultural crops in all regions of the world and cause serious economic damage (Figure 7). Because weed species have contrasting morphology, physiology, and life histories, these species will likely vary in their degree of response to CO_2 enrichment and other global environmental changes, which will occur nonuniformly in different parts of the world. Many weeds will increase their distribution and seriousness, whereas others may decrease in importance as a threat to agricultural ecosystems.

One analysis of the world's most noxious weed species found that the six most serious weeds and 9 of the 12 most serious weeds use the C_4 photosynthetic pathway (Holm et al. 1991; Wang and Mohan 2008), probably because the world's agriculture is mostly concentrated in warmer regions, where C_4 species have a competitive advantage over C_3 species. On one hand, higher temperatures resulting from increased atmospheric CO_2 may help these warmer-climate weeds expand toward higher latitude and greatly increase their geographic distribution (Patterson 1995). On the other hand, C_3 plants are generally more responsive in photosynthesis and growth to CO_2 enrichment than C_4 plants (see Section 2.03.1 Introduction). The outcome of the competition between C_3 and C_4 species will therefore be determined by the interaction of a number of factors in addition to CO_2 enrichment.

Another factor that will likely interact with CO_2 enrichment in the atmosphere in affecting undesired plant species is the shift in human populations around the world. Changes in the geographic distribution of humans will cause change in the use of particular crops in agriculture. As a result, the occurrence and seriousness of weeds will change because weeds are usually a problem specific to a certain crop species (Wang and Mohan 2008).

Although the precise effects of increased atmospheric CO_2 on particular weed species are difficult to predict, it is of ecological and economic significance to improve our understanding of the effects of CO_2 enrichment and other environmental changes on weeds and their interactions with crops (Wang and Mohan 2008).

One example of a geographically wide-spread weed species whose response to elevated CO_2 has been carefully studied is the common dandelion (*Taraxacum officinale*). Dandelion plants grown at elevated CO_2, produce a larger number of fruits per plant (Figure 8). Under elevated CO_2, their fruits also show morphological characteristics that favor increased enhanced

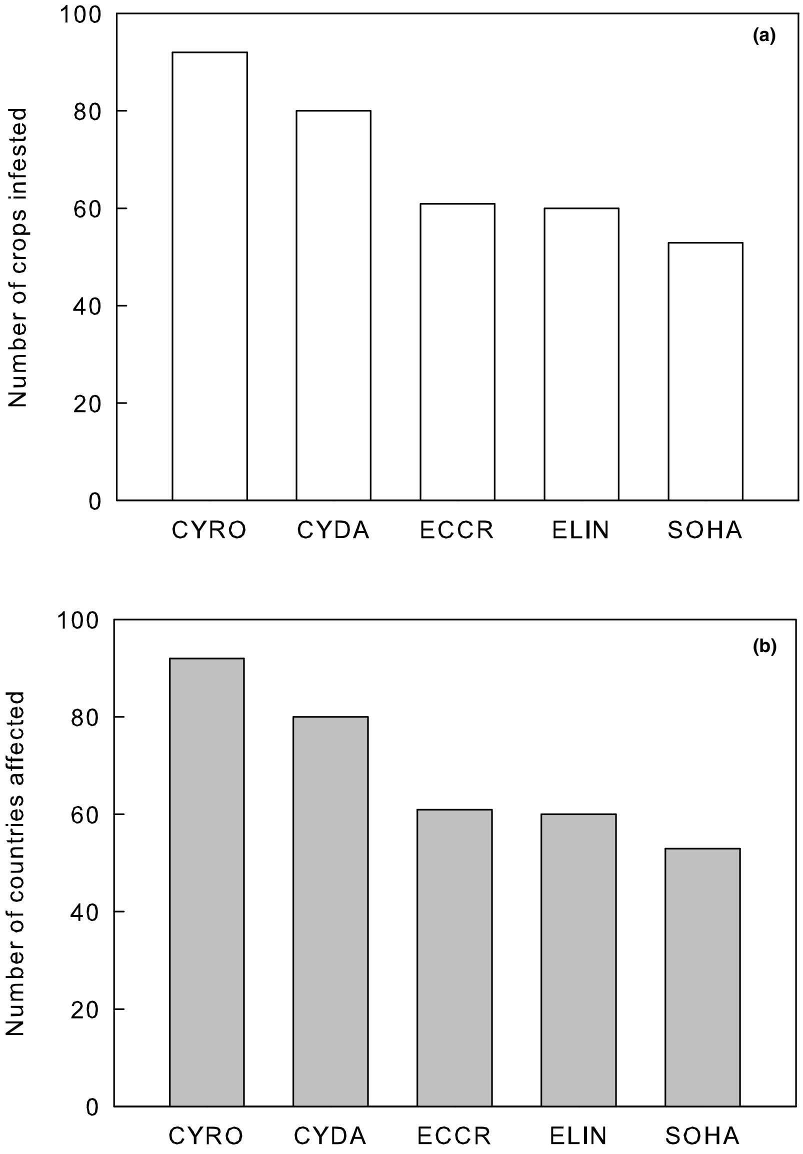

Figure 7 Seriousness of major weeds in terms of crops infested and the number of countries that reported the species as a major weed. CYRO, *Cyperus rotundus* (purple nutsedge); CYDA, *Cynodon dactylon* (bermudagrass); ECCR, *Echinochloa crus-galli* (barnyardgrass); ELIN, *Eleusine indica* (goosegrass); SOHA, *Sorghum halepense* (johnsongrass). Seriousness of weeds was extracted from Holm, L. G., D. L. Plucknett, J. V. Pancho, and J. P. Herberger, 1991: *The World's Worst Weeds: Distribution and Biology*. Krieger Publishing Company, 609 pp.

potential for long-distance dispersal by wind. Their seeds are also larger and germinate more readily than those grown under current atmospheric concentrations of CO_2. All of these changes suggest the potential for increased spread and increased density of dandelion populations under elevated CO_2 (McPeek and Wang 2007). Dandelion also has a number of nonreproductive features such as a high growth rate and competitive ability, which are likely to increase its success as CO_2 concentrations increase.

Another undesirable plant species that appears to receive a large boost from increasing atmospheric CO_2 is poison ivy, *Toxicodendron radicans*. Both FACE and growth chamber studies have shown growth stimulation by elevated CO_2 to be greater than for C_3 species in general (Mohan et al. 2006; Ziska et al. 2007). A shift under elevated CO_2 toward increasing production of the most virulent forms of the irritating agent urushiol has also been observed (Mohan et al. 2006). As with dandelion, poison ivy therefore appears to have the potential to become even more widespread and noxious in an enriched CO_2 world (McPeek and Wang 2007; Ziska et al 2007).

4.04.4 Summary

Increasing concentrations of atmospheric CO_2 over the next decades can be expected to have important implications for plant physiology and growth. Many plant species are likely to exhibit higher rates of photosynthesis and growth, decreased

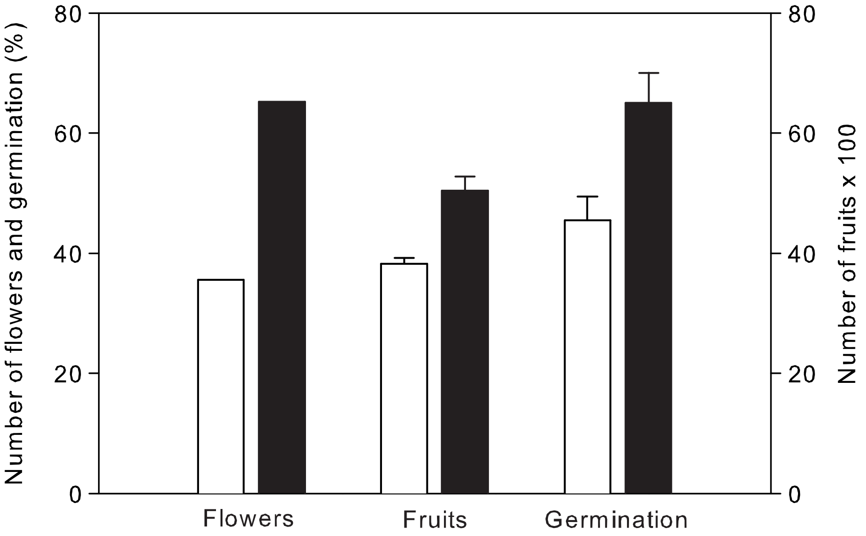

Figure 8 Number of flowers per plant, number of fruits per plant and germination percentage of fruits in dandelion plants grown at ambient (unfilled bars) and elevated (filled bars) CO_2. Data were extracted from McPeek, T. M., and X. Z. Wang, 2007: Reproduction of dandelion (*Taraxacum officinale*) in a higher CO_2 environment. *Weed Sci.*, **55,** 334–340 and re-analyzed.

water consumption and changes in tissue chemistry, including increased concentrations of nonstructural carbohydrates, and decreased concentrations of protein and minerals. These effects of increasing atmospheric CO_2 are not expected to be uniform among plant species. In particular, the physiological characteristics of legumes and plants that utilize the C_4 variant of photosynthesis suggest that these types of plants will show responses distinct from those of other species. The most likely threats to ecosystem services as a result of increased atmospheric CO_2 are (1) decreased crop and forage food values caused by decreased concentrations of proteins and minerals and (2) undesirable changes in plant community composition, including increases in populations of some major weed species.

4.05.1 Introduction

The ongoing global redistribution of species is one type of environmental change that we are experiencing. Climate, eutrophication, ocean acidification, and land use change are other types of change that are occurring. None of these changes are occurring in isolation. They all are interacting to produce a myriad of changes, including local, regional, and global changes in flora and fauna (Davis 2009; Perrings et al. 2010; Pereira et al. 2010). Ultimately, this means that the effects of different drivers of environmental change cannot be studied in isolation. They must be studied using an integrated approach (Walther et al. 2009). This approach can challenge or redefine traditional paradigms that may have developed when the drivers were studied separately.

For example, climate effects may blur the boundaries between native and non-native species (Thomas and Ohlemüller 2010). Some species could enter a new region with human assistance while others could enter via natural migration due to altered weather patterns. Both will be new species to the area and both could cause problems. Moreover, a native species that may not have caused problems in a region could become invasive. A good current example of this is the explosive spread by the native mountain pine beetle and the enormous amount of tree mortality it is currently causing in areas of the Rocky Mountains, where it was not found before (Robins 2008). Conversely, a prior native invasive species may become less of a problem. Esper et al. (2007) documented 123 outbreaks of the larch budmoth in Southern Switzerland during the period 832–2004 C.E., with a mean period between outbreaks of 9.3 years, with never a gap between outbreaks of more than two decades. Between 1981 and 2007, not a single outbreak was recorded and the authors hypothesized that increasing air temperatures in this region during this period may be at least partly responsible for the absence of outbreaks.

Non-native species, like native species can be beneficial, harmful, or negligible in their effects. When a non-native species causes harm of some sort, it is typically described as invasive. Thus, the term ‘invasive species’ normally refers to non-native species that are producing consequences that humans do not like and deem harmful. The harm caused by non-native species is usually described as one of three types: threats to human health, economic harm, and ecological harm. Of the three, most people would likely agree that organisms that threaten human health, primarily introduced pathogens that are the causes of emerging diseases throughout the world, should be our first priority, followed probably by species that cause or threaten to cause great economic harm. One type of economic harm is the damaging or compromising of ecosystem services. Since the replacement of ecosystem services exacts an economic cost for a society, harm to ecosystem services is considered a type of economic harm in this chapter. Ecological harm would consist of ecological effects that do not have an economic cost, or threaten human health, but may still be deemed undesirable. Also, some species may cause more than one type of harm, and/or the type of harm might change over time. For example a species causing just ecological harm at the outset may begin to produce economic harm as time proceeds.

Among invasive species, introduced pathogens almost certainly pose the greatest threats to human well being and that of other organisms, having shown over and over their ability to devastate crops (e.g., 19th century potato blight in Ireland), livestock (e.g., rinderpest outbreaks in Africa in the 19th and 20th century), humans (e.g., 1918 influenza pandemic), and other plant and animal species (e.g., ongoing chytrid fungus epidemic killing frogs worldwide). However, introduced plants and animals also can cause great economic harm, often by damaging ecosystem services. In this chapter, I review some of the harm done to ecosystem services by non-native invasive plants and animals, as well as threats of future harm, and how climate is mediating these effects, sometimes exacerbating them and sometimes mitigating them.

There are dozens of types of ecosystem services, but they are commonly grouped into four categories: provisioning, regulatory, supporting, and cultural (MA 2005). Examples of provisioning services provided by nature are food, timber, fiber, and

http://dx.doi.org/10.1016/B978-0-12-384703-4.00405-6

water. Regulating services include pollination, flood control, water purification, and processes reducing threats of disease and harm from climate. Tourism, recreation, aesthetics, and spirituality constitute cultural services, while supporting services include processes such as nutrient cycling and soil formation, which support the other services (MA 2005). The impacts of invasive plants and animals on these ecosystem services, as well as examples of how climate sometimes interacts with species introductions to produce these effects, are described separately in the following sections.

4.05.2 Impacts of Invasive Species on Ecosystem Services

4.05.2.1 Provisioning Services

In several cases, introduced tree species have been found to reduce surface water availability, particularly when replacing native herbaceous species, due to increased water uptake and evapotranspiration. In parts of New Zealand uplands, native tussock grasslands help provide water supplies for humans living at lower elevations. Due to their morphology and physiology, the grasses are efficient at capturing water, whether rain, fog, or snow, and they exhibit low rates of transpiration. As a result, the grasses released 64–80% of the precipitation to surface waters that were then accessible to humans (Mark and Dickinson 2008). In 1980, *Pinus radiata* was introduced to provide a timber resource. Twenty five years later, surface runoff, which provides water resources for the local residents, had declined by 50% (Mark and Dickinson 2008). A similar phenomenon occurred in South Africa, where the encroachment of *Pinus*, *Eucalyptus*, and *Acacia* in native upland environments similarly reduced water yield (Van Wilgen et al. 2008). A global meta-analysis of water use by native and non-native invasive plants showed that while there was little difference in sap flow rates, at the ecosystem scale, invasive-dominated ecosystems were more likely to exhibit higher sap rates per unit ground area than native-dominated ecosystems (Cavaleri and Sack 2010). On the other hand, comparisons between evapotranspiration rates between ecosystems dominated by invasive versus native species found no consistent differences (Cavaleri and Sack 2010).

For many people in the world, fish is a primary part of their diet. Evidence has shown that the introduction of some non-native fish or other organisms influence the economic value of the native fish used for food by altering the age-dependent survival probabilities. If the non-native fish prefer the larger native fish, then selection favors smaller fish and earlier maturation in the prey population, a process known as ‘stunting’ (Lehtonen 2002), which then directly impacts this primary food resource for local people. The dramatic negative impact on the North American Great Lakes fisheries by the sea lamprey, *Petromyzon marinus*, is well known. During the 1940s and 1950s, populations of the native lake trout, white fish, and chub collapsed and with it the associated fishing industry. Prior to the introduction of the sea lamprey into lakes like Michigan and Superior, annual US and Canadian harvests of lake trout exceeded 15 million pounds. By the early 1960s, the total Great Lakes harvest had dropped to 300 000 pounds, with harvests in some of the lakes being virtually nil (Great Lakes Fisheries Commission 2000).

The introduction of the comb jelly (*Mnemiopsis leidyi*) into the Black Sea is estimated to have reduced the anchovy harvest by 10% between the mid-1980s and the early 1990s (Travis 1993). Impacts on local fish populations were among the highest concerns when zebra mussels, *Dreissena polymorpha*, were introduced into North America and began to spread. Clear impacts on fish have been recorded, but the impacts are not always consistent. Commonly, planktivores decline following the introduction of the mussels, which deplete plankton populations. Fish feeding on benthic resources often increase in numbers but, many fish are able to utilize both pelagic and benthic resources and are able to buffer the changes produced by the mussels (Higgins and Van der Zanden 2010). Data have shown that the size of the impact, and in some cases, even the direction of the impact, varies across ecosystems and fish species (Strayer 2009), making it impossible at this point to be able to make any clear predictions of impacts on fish populations in a lake when colonized by zebra mussels.

The South American plant, *Salvinia molesta*, is recognized as one of the most widespread invasive aquatic plant species in the world, (Room 1990). It is able to double in cover every 3–4 days and can quickly infest entire freshwater systems (Room and Thomas 1986). In a short time, *S. molesta* can threaten local water supplies, and by making waterways unnavigable, prevent access to fish, which constitute a primary part of the diet of local residents (Stone 2011). In Papua New Guinea, entire villages had to be abandoned. The residents moved once local waterways were infested with this species (Stone 2011). Similar harm has resulted from the introduction of water hyacinth, *Eichhornia crassipes*. In Lake Victoria, its introduction has been documented to reduce fish harvests, water supplies, and in general, obstruct navigation through the waterways (Kasulo 2000). Other invasive species have undermined local water quality. In Southeast Asia, the Golden Apple Snail, *Pomacea canaliculata*, has converted what were originally naturally water-purifying wetlands into algal-dominated systems (Carlsson et al. 2004). Introduced carp can have a similar effect, transforming mostly clear lakes and streams into turbid systems (Angeler et al. 2002).

The negative impacts on timber resources of introduced insects have been well documented. In some instances, evidence suggests that warming is exacerbating the negative effects of these forest insect pests by permitting additional generations (Gomi et al. 2007). The hemlock wooly adelgid, *Adelges tsugae*, has been a primary source of mortality for the eastern hemlock, *Tsuga canadensis*, in many eastern North American populations (McClure and Cheah 1999; Lovett et al. 2006). Other prominent invasive insects in North America which undermine timber resources and/or services such as shade and cooling in urban areas, include the Asian long-horned beetle (Haack et al. 1996; Becker 2000), the balsam woolly adelgid (Hain 1988), the gypsy moth (Davidson et al. 2001), and the emerald ash borer (McCullough and Katovich 2004). The Asian long-horned beetle is also a timber pest in Europe (Vilà et al. 2010). The emerald ash borer arrived in this author’s neighborhood in 2009, which represented its first documentation in the state of Minnesota. The state of Minnesota is estimated to have 900 million ash trees, many of them growing in forests, but many also planted abundantly in cities to replace elms which had died due to the Dutch elm disease during the 20th century. Current estimates of the damage expected from the emerald ash borer, including loss of timber and costs to remove trees from yards, parks, and city streets, range from the tens to the hundreds of millions of dollars for Minnesota alone, and the species has spread throughout the entire upper Midwest, meaning regional costs will be much higher.

Introduced earthworms in Great Lakes forests of North America are known to have dramatically altered the physical and biogeochemical properties of the soil and litter layer, to the detriment of many native herbs (Frelich et al. 2006). They are also believed to be responsible for some of the declines in tree seedling success (Hale et al. 2006), which means they may constitute a threat to timber resources as well. Of course major threats to timber resources also come from native species. The southern pine beetle, *Dendroctonus frontalis*, is considered the most destructive insect pest of pines in the southern US. Price et al. (1992) estimated that the species had caused $900 million of damage between 1960 and 1990. The mountain pine beetle, *Dendroctonus ponderosae*, may be killing more trees in North America at this time than any other species. Perhaps due to a warming climate, the species has spread northward into areas where it had not previously been found, or at least where it had never been a large problem, such as portions of British Columbia. This raises an interesting question: if a native North American species expands its range on its own, should it be considered a non-native species in its new range? For the ecosystems and species in the new range, it makes little difference how the species got there. There is no clear scientific answer to this question. Individuals will disagree as to whether such a species should be considered native or non-native, which illustrates the increasing ambiguity that is developing, as these different global change drivers interact with each other. Distinct categories that may have made sense when a driver is studied separately can begin to break down when studied in the context of another driver, for example, invasive species studied in the context of climate change.

Some non-native species compete for forage in pasturelands where they have been introduced, thereby reducing the productivity of domesticated grazers. Wilson (1995) estimated that foraging by rabbits in Australian pasturelands costs the country $600 million annually. That introduced insects and weeds cause billions of dollars of damage to crops each year throughout the world is well known and will not be further discussed here. While insects (and pathogens) and weeds are normally the primary threats to crops, in some cases other animals cause significant harm as well, some of which are introduced. For example, the coypu (*Myocastor coypus*) causes extensive crop damage in parts of Europe (Bertolino and Genovesi 2007).

4.05.2.2 Regulating Services

Pollination of many crop and orchard species is a large ecological service provided by insects. While many studies of the effects of introduced insects on plant pollination have not focused on food plants, the results indicate the clear possibility that pollination extent and efficiency could be compromised by introduced species (Traveset and Richardson 2006). This can happen in several ways. Introductions of new flower visitors may reduce the visitation rates by native species, which may be more effective pollinators (Gross and Mackay 1998; Hansen et al. 2002; Dohzono et al. 2008). Introduced predators may reduce the size of native pollinator populations (Kelly et al. 2007). Also, introduced plants could compete with the native plants for pollinators (Brown and Mitchell 2001). Of course, it must be acknowledged that a primary pollinator of many crop and orchard species is the honey bee, *Apis mellifera*, an introduced species itself. The influence of non-native plants on native pollinator populations is an interesting question and some of the answers have been surprising. In some instances, non-native plants have been found to support native pollinators by providing nectar and pollen that may have been declining in the environment, due to a decline in some of the native plant species, or due to various factors, for example, land use change and climate change (Hughes et al. 2006; Kenta et al. 2007). On the other hand, non-native plants may compete with native plants for pollinators resulting in the decline of reproductive success of some of the native species (Morales and Traveset 2009).

Impacts on the global carbon cycle, particularly processes that influence the effects of natural carbon sinks, represent another type of regulating service. Studies on North American prairies have shown that the introduction of new plant species can reduce the ability of the system to sequester carbon. In particular, studies showed that the grasslands stored less carbon when crested wheatgrass, *Agropyron cristatum*, was introduced and replaced many of the native grass species (Christian and Wilson 1999; Curtin et al. 2000). A similar finding was documented in Hawaii where the replacement of native forests with non-native grasslands resulted in a 93% reduction in above-ground biomass, and consequently a dramatic reduction in the above-ground carbon storage (Litton et al. 2006). On the other hand, Wardle et al. (2007) found that the introduction of invasive predators on islands promoted ecosystem carbon sequestration.

One of the most important threats to ecosystem services involves the harm to grazing animals by some introduced plants. Leafy spurge (Leistritz et al. 1993), yellow starthistle (Eagle et al. 2007), and knapweed (Ridenour and Callaway 2001) are estimated to cost landowners and ranchers well more than $100 million per year (Duncan et al. 2004; and Eagle et al. 2007). Some introduced vertebrates can also diminish the value of pastureland.

Invasive seaweeds are known to produce population, community, and ecosystem effects, although long-term studies are still mostly lacking (Williams and Smith 2007). For example, while the invasive seaweeds may increase primary productivity, it is not yet known whether this may lead to increased abundances of species that might be utilized as food by local human residents (Williams 2007). In some cases, the opposite is believed more likely. Eutrophication is a common consequence of invasive seaweeds, which can trigger algal blooms, which in turn can compromise the productivity of other organisms that humans may use for food (Williams 2007). Introductions of other marine organisms have also been documented to undermine ecosystems services, including decline in food production and decline in property values (Williams and Grosholz 2008). Introductions into freshwater systems can have similar diverse consequences, from affecting particular species to affecting ecosystem processes (Ricciardi and MacIsaac 2011). These impacts include effects on nutrient cycling and primary productivity and significant alteration of the habitat (Ricciardi and MacIsaac 2011). In one instance, the introduction of a non-native planktivorous fish resulted in three native planktivores to shift their diets from zooplankton to benthic organisms near shore. This resulted in an increase in mercury concentrations in all three species (Eagles-Smith et al. 2008). As is the case in estuarine and marine systems, introductions of non-native freshwater plants can significantly affect ecosystem services, including altering water quality (Rommens et al. 2003)

There is considerable evidence that emergent diseases have several root causes, including the direct transporting of pathogens from one region to another, habitat loss or human movement into wild habitats (both of which can increase the contact of humans with novel pathogens), and the decline in biodiversity (Pongsiri et al. 2009), which sometimes can be caused by invasive species. Biodiversity decline can contribute to the spread of disease by the loss of predators of common animal hosts for the disease, as well as dramatic declines in the numbers of animal hosts. (Pongsiri et al. 2009). The previous sentence may appear self-contradictory, but if too many animal hosts are infected than the frequency of human contact with the pathogen will increase. On the other hand, if the number of typical animal host declines too much, then the pathogens need to adopt alternative hosts, for example, humans. Some introduced animals can increase the threat of human disease by creating more breeding sites for the hosts of the pathogens. For example, through their rooting foraging behavior, feral pigs in Hawaii create depressions that can fill with water, thereby providing breeding sites for disease-carrying mosquitoes (Atkinson 1995). Similarly, the tsetse fly (*Glossina* spp.) has been found to utilize stands of an invasive tree, *Lantana camara*, as a new habitat (Leak 1999).

Some introduced species threaten flood control or erosion efforts. The great shipworm (*Teredo navalis*) has damaged dikes and other flood protection installments around the Baltic and North Seas (Leppäkoski et al. 2002). In Europe, the coypu increases erosion along rivers through its herbivory and burrowing into the banks (Bertolino and Genovesi 2007). Other non-native species have increased erosion, including introduced vertebrates on some islands (North et al. 1994) and the replacement of native plant species by non-native plants, the latter which proved to be less effective in erosion control (Lacey et al. 1989). Many invasive plant species have altered fire regimes, some of which can come with very high economic costs. It is estimated that the increase in fire frequency in the Everglades and Australia due to the introduction of a non-native tree, *Melaleuca quinqeunervia*, will cost hundreds of millions of dollars (Serbesoff-King 2003).

4.05.2.3 Supporting Services

In the Great Lakes region of the US, non-native earthworms are believed to be affecting such fundamental ecosystem processes such as soil organic matter decomposition, carbon cycling, and nutrient cycling (Hendrix et al. 2008). Interestingly, a model of the earthworm effects on primary productivity suggested that the earthworm presence may increase primary productivity through the conservation of nutrients in the ecosystem (Barot et al. 2007). Considerable data exist showing how species traits can substantially affect various ecosystem processes in freshwater systems, including nutrient cycling, levels of dissolve oxygen, and water clarity (Vaughn 2010). This indicates that introductions of new species have the possibility of significantly altering some of these processes. One of the best examples of introduced species altering ecosystem processes involves the introduction of non-native mussels into North American freshwater systems. For example, introductions of zebra mussels, *Dreissena polymorpha*, usually cause dramatic declines in phytoplankton and small zooplankton, which substantially increase water clarity, as well as levels of soluble nitrogen and phosphorus, which in turn have sometimes resulted in significant increases in the growth and abundance of macrophytes (Caraco et al. 1997, 2000).

On islands, major sources of nutrient inputs come from seabirds during the breeding season, when they transport nutrients acquired from ocean food to the islands via their feces. A number of recent studies have shown that the introduction of non-native predators, such as foxes and rats, can dramatically reduce the transfer of nutrients from the ocean to the island, thereby significantly affecting soil fertility, which in turn influences the type of vegetation that dominates (Fukami et al. 2006; Wardle et al. 2007). Wardle et al. (2009) showed that the introduction of the predators and the consequent disruption of the nutrient transfer between ecosystems reduced leaf nitrogen levels and reduced the rate of litter decomposition.

4.05.2.4 Cultural Services

Non-native plants have always been popular among gardeners who enjoy the added diversity and aesthetics that they provide to the environment. Warming climates are already providing opportunities for many popular plant cultivars to be planted further north. In Europe, some garden species are being successfully planted and maintained as far as 1000 km north of their recently historical range (Van der Veken et al. 2008). At the same time, other non-native species may threaten other cultural services. Examples include non-native plants infesting waterways and interfering with boat traffic and tourism (Eiswerth et al. 2005). Impacts by some aquatic invasive species that reduce desired fish populations or impede boat travel or otherwise interfere with tourist activities will significantly reduce the public enjoyment of these environments, not to mention the economic losses experienced by communities for which tourism was a primary industry. Of course what is deemed environmental harm by one person may be deemed a cultural service by another. For example, while the Minnesota European environmentalists and nature lovers were decrying the introduction and spread of garlic mustard (*Alliaria petiolata*) into Minnesota forests, the local Hmong population was out harvesting the species as a food source, thereby retaining their cultural practice of harvesting wild plants for food.

4.05.3 Looking Ahead: Climate and Its Effects on Invasive Plants and Animals

Depending on the species, climate facilitates or inhibits the spreading of some invasive species (Bradley et al. 2010, Diez et al. 2012). Regional changes in precipitation and temperature regimes can cause expansions, contractions, or shifts in species' ranges depending on the direction of the changes in temperature and precipitation and on how the individual species respond to these changes. It is likely that the spread of certain types of species would be more likely to be more sensitive to any alterations in regional and local climate change and that certain types of environments may be particularly vulnerable to species introductions influenced by climate.

4.05.3.1 Species Sensitive to Enhanced Spread

The likelihood that a species will spread into and establish in a new area is a function of how many propagules are introduced into the new area and the likelihood of establishment by individual propagules (Leung et al. 2004), the latter of which is due to how well the traits of the species match up with the ecological conditions in the new environment (Davis 2009). The nature of the altered conditions in the new environment due to climate will open the door to some species more than others. For example, if precipitation in an area increases, this may make new resources available to plants, not only water, but also possibly nutrients, the uptake of which may have been water limited in the past. Plant species adapted to take advantage of high resource conditions will be favored in these environments, assuming the species are able to disperse, or be transported, into them. In both plants and animals, non-native species that either have great natural dispersal abilities or are regularly transported by humans in one way or another would be able to best keep pace with any alterations geographically in weather patterns.

4.05.3.2 Particularly Vulnerable Environments

Some regions of the world are more vulnerable to species introductions if weather patterns change. These include high altitude environments and high latitude regions. High altitude environments provide several important ecosystem services including water supplies and recreational opportunities (Körner 2004). To date, many high altitude sites have yet to experience high rates of species introductions, probably due to a combination of low levels of propagule pressure and habitat disturbance, both a result of low amounts of human activity in these environments. However, more than one thousand species of non-native plants have established in high altitude sites throughout the world and while local species richness may increase at some sites, there is growing concern that some of these plants may negatively affect the highly valued ecosystem services provided by these environments (Pauchard et al. 2009). For example, the replacement of herbaceous or shrub vegetation by trees might result in increased evapotranspiration and less water export down to lower elevations (Mark and Dickinson 2008). Moderating temperatures would inevitably make it easier for many non-native species to spread into higher altitude sites. Also, the spread of non-native plants is likely increasing due to the increased connectivity between high altitude sites, which is resulting from increased movements by humans between sites, often facilitated by the construction of roads and/or recreation areas. The establishment of some non-native plants at these higher elevations may also be facilitated by atmospheric nitrogen deposition (Price 2006), bringing in yet another environmental change driver to interact with invasive species and climate.

Arctic regions have been reported to have experienced dramatic temperature increases over the past few decades, exceeding recent historical trends by 1.4 °C (Kaufman et al. 2009), although other data questions the magnitude of this increase [Alexeev et al 2012]. If surface temperature increases over the Arctic, which then warm the soils, and melt the permafrost, snow and ice, this would transform the terrestrial and marine arctic environments and making them amenable to more species. For example, it is estimated that 219 shallow water mollusk species in the northern Bering Sea have the potential to spread into the North Atlantic due to warming arctic waters without any human assistance (Vermeij and Roopnarine 2008). Increase shrub growth has been documented (Sturm et al. 2001) and the spread of other plants northward, some facilitated by humans and some not, is assumed. Like plants everywhere, they will alter ecosystem processes such as nutrient cycling and carbon sequestration. Some of the changes we may view as enhancing ecosystem services; some we may not. Antarctica currently has only two native vascular plants, Antarctic hairgrass, *Deschampsia antarctica*, and Antarctic pearlwort, *Colobanthus quitensis* (Caryophyllaceae). If surface temperatures warmed and increasing human travel to Antarctica by scientists and tourists, new plant species, as well as animal species, would be arriving soon, if they have not done so already. The number of species in high latitude regions would almost certainly increase since the number of introductions will likely exceed the number of extinctions, perhaps substantially. It is also expected that hybridization will be common between some of the new and long-term residents (Vermeij and Roopnarine 2008).

Environments experiencing increased resource availability are particularly vulnerable to the establishment of new species (Davis et al. 2000). As described above, if climate permits increased water and/or nutrient availability in an environment, it would be more invasible to many plant species. Similarly, if the local and regional climate results in an increase in primary productivity, the increase of food availability would likely make the habitat more invasible for herbivores.

4.05.3.3 Environments Not Likely to Be Vulnerable to the Introduction of Invasive Species

No environment is immune to the introduction of new species. Evidence has shown that all environments are invasible to some extent (Davis 2009). While climate effects may change the invasibility of certain environments with respect to some species, all terrestrial, freshwater, and marine coastal environments would experience species introductions in the future. However, there is one group of environments that probably would be less affected by the interaction of species introductions and any long-term alterations in weather patterns than others. This is not because these environments are less invasible, but rather because they are already occupied mostly by non-native species. These are areas where human disturbance has been high for a long time, such as urban areas and agricultural lands. Undoubtedly, there would be some exchange of species due to climate, with some non-native species being replaced by other non-native species. However, these environments would not experience dramatic shifts in the relative abundance of long-term residents and newly arrived species, as would be the case in many forests, grasslands, wetlands, rivers and lakes, and coastal marine systems, which have currently experienced less intense human disturbance—hence typically are inhabited by proportionately fewer non-native species than are the highly anthropogenically disturbed environments.

4.05.3.4 Challenges in Distinguishing Harm from Change

There is an emerging consensus that invasive species and climate can no longer be studied as independent drivers (Davis 2009; Walther et al. 2009; Thomas and Ohlemüller 2010). Climate influences which species are able to live in particular areas and also what their ecological effects are. Native species that historically may have been beneficial, or at worst a periodic annoyance, could become invasive and very harmful, as is happening with the mountain pine beetle in North America. Some native species that may have been providing important ecosystem services may decline in numbers or even disappear from a region if weather patterns change. In this case, some non-native species may prove to be highly desirable if they are able to replace those ecosystem services and efforts may be undertaken to increase and facilitate their establishment (Walther et al. 2009). As emphasized by Thomas and Ohlemüller (2010), the traditional perspective that native species are 'good' and alien species are 'bad,' which dominated conservation and alien control programs is no longer viable.

The mere characterization of species as native and non-native is believed by many to becoming a dubious exercise, which will only increase in dubiousness as the years go by (Davis 2009; Thomas and Ohlemüller 2010; Davis et al. 2011), particularly since any alteration in weather patterns could shift the ranges of species resulting in new mixtures of species. Pejchar and Mooney (2009) emphasized that many invasive species have turned out to have positive impacts for local residents, and urged caution in making quick and knee-jerk assumptions about the effects of introduced species. Ultimately, determining harm is not a scientific decision, even if scientists are the ones making the decision. This represents a social decision, and one in which different stakeholders may honorably disagree. For example, herbalists may view introduced plants as promising new medicinal value and urban landscape architects may view non-native plants as being able to provide valuable ecosystem services to urban environments (del Tredici 2010). This important fact is recognized by the National Invasive Species Council in the US: 'Some non-native species are considered harmful, and therefore, invasive by some sectors of our society while others consider them beneficial. This discontinuity is reflective of the different value systems operating in our free society, and contributes to the complexity of defining the term *invasive species*' (NISC 2006).

I do not believe we can proceed with definitions of negative impacts from invasive species similar to the following: 'Negative impacts documented included, for example, predation, competition, change in fire regimes, displacement of native species, and modification of succession processes' (MgGeoch et al. 2010). Under such broad definitions, any non-native species could be declared invasive. If almost any ecological impact is enough to consider a species invasive, then almost any non-native species could be considered a threat to ecosystem services, since it takes little imagination to connect some ecological change with some potential threat to an ecosystem service. As a society, we need to be discriminating. We need to be slow to characterize any species as invasive, since that essentially obligates society to spend resources to fix 'the problem.' We need to be sure not to confuse harm with change. We need to focus on those species, both native and non-native, that are truly causing harm or are threatening to cause harm, to ecosystem services. The same holds for climate. Depending on the location and its effects, alterations in long-term weather patterns by itself is not necessarily harmful, and in fact may be regarded as beneficial by people in some places due to its effects, for example, by increasing food production due to increased growing seasons and/or precipitation. Similarly, the changes resulting from the interaction of climate and species introductions should not automatically be considered harmful.

4.05.3.5 Managing Our Priorities

We should stop judging species on their origins and instead focus more on their effects (Davis et al. 2011). Like native species, some non-native produce desirable effects, some are mostly benign, and some, the ones we call invasive species, cause problems, sometimes severe problems. It is of the utmost importance that we distinguish between severe problems and smaller problems, or even question whether we are calling simple change a problem. Any new species will cause some ecological effect. It may affect nutrient cycling, it might compete with other species, it might be prey on other species, but it will always have effects. This means that as long as we study hard enough, we will be able to document ecological effects of every single non-native species. Clearly, society does not have the resources to fund claims amounting to little more than personal preferences. Society needs to retain its resources so that they can be used to manage and mitigate the significant harm to ecosystem services produced by some non-native species.

Given limited social resources, scientists, land managers, and policy makers owe it to the public, who are usually providing the funding, to seriously question whether or not action should be taken to eradicate or manage a non-native species or try to mitigate its effects. Specifically, the following seven questions should be asked.

1. Do the net effects on ecosystem services by this species truly constitute harm, or can the effects be regarded simply as change?
2. Can we learn to live with this species?
3. If we decide we must manage or control it in some way, does an effective management approach actually exist?
4. Does this management approach make sense in the context of the spectrum of climate effects on the environment now and what is possible in the future?
5. If an effective management approach does exist, are we confident that the benefits we will receive from the management intervention will exceed the costs (with costs including not only dollars, but other inevitable effects on the environment and other species, including ourselves)?
6. Are we sure we would not prefer to spend these resources on some other environmental project or initiative?
7. Are we confident we are not throwing money down the drain?

4.05.4 Conclusion

Ultimately, our decisions regarding what to do with invasive species become economic. Of the thousands of non-native species that have entered and will continue to enter our countries in the future, we will only have the resources to manage a small proportion of them. We need to make smart decisions, which means we need to begin using the term invasive more sparingly. Like it or not, these new species are not going back. No matter what we call them, they are our new residents, except in extremely rare cases when an all out eradication campaign is undertaken and is successful, for example, the eradication of a deadly human pathogen from a country. Clearly, when the damage, or threatened damage, by plants and animals to ecosystem services is very high and clearly outweighs the costs and harm associated with whatever management measures will be undertaken, society needs to invest its resources to try to control these.

Although it sometimes seems that non-native species are considered as a kind of toxic or nuclear waste (e.g., with threats of an invasional meltdowns), or some kind of demons that threaten life as we have known it, we are talking about species—plants and animals, our fellow inhabitants of planet earth. As described by Peter del Tredici (2010) in his book 'Wild Urban Plants of the Northeast,'

> The confluence of climate change and urbanization—acting in concert with the global spread of species—has set the stage for spontaneous vegetation to play a major ecological role in the human dominated landscape (Ziska et al. 2004; Christopher 2008; George et al. 2009). Regardless of how humans feel about this brave new ecology, the plants described in this book are well adapted to the world we have created, and as such, are neither good nor bad—they are us.

In the end, we really have little choice. Climate influences and species introductions will continue into the foreseeable future no matter what humans decide to do or not do. We will continue to devote considerable resources to try to protect our ecosystem services from threats from particularly harmful invasive species. However, in many instances, rather than trying to manage the endless introductions, we would do better to try to manage our attitudes toward them. Although we do have some ability to shape the direction and combined impacts of climate and species introductions, ultimately, like other species, we are going to have to adapt and accommodate these changes into our lives, economies, and cultures.

Glossary

Bioclimatic model A model that integrates knowledge of physics, ecology, and physiology to predict how ecological systems will change in the future in response to environmental factors.

Climate change One definition used is that it is a significant and lasting change in the statistical distribution of weather patterns over periods ranging from decades to millions of years. In this chapter, we focus on the climate variables of temperature and precipitation. More generally, climate change refers to alterations in the climate system which is the system consisting of the atmosphere, hydrosphere, lithosphere, and biosphere, determining the Earth's climate as the result of mutual interactions and responses to external influences (forcing). Physical, chemical, and biological processes are involved in interactions among the components of the climate system (NRC 2005).

Infectious disease Illness resulting from the infection, presence, and growth of pathogenic biological agents in an individual host organism.

Macroparasite A parasite that grows in its host, but multiplies by producing infective stages that are released from the host to infect new hosts. They are often intercellular or live in body cavities, rather than within the host cells. Examples include ticks, mites, nematodes, and trematodes.

Microparasite A parasite that completes its life cycle within a single host and can be transmitted directly between hosts. They often reproduce within a host's cells and are generally too small to be seen with the naked eye. Examples include viruses, bacteria, and fungi.

Physiology The study of an organism's vital functions, including growth and development, the absorption and processing of nutrients, the synthesis and distribution of proteins, and other organic molecules, and the functioning of different tissues, organs, and other anatomic structures.

4.06.1 Introduction

Ongoing increases in human population density have led to increased agricultural expansion, pollution, introduction of exotic species, and overharvesting of resources. Two of the most pressing concerns currently confronting society are local impacts of climate and the emergence of infectious diseases. According to the Intergovernmental Panel on Climate Change (IPCC 2007), observed changes in climate patterns are due in part to the effects of anthropogenic activities. Documenting the consequence of these changes for species' distributions, phenologies, and biodiversity has become a major focus of biologists (Walther et al. 2002; Parmesan 2006; Parmesan et al. 2011; Parmesan and Yohe 2003). Growing evidence indicates

http://dx.doi.org/10.1016/B978-0-12-384703-4.00406-8

that such effects would manifest across multiple scales of biological organization, ranging from individuals to ecosystems (Post et al. 2009; Hoegh-Guldberg and Bruno 2010; Woodward et al. 2010). Simultaneously, disease ecology has received increased attention due to the emergence of many new infectious diseases (Daszak et al. 2000; Woolhouse 2002; Jones et al. 2008). While the emergence of human diseases (e.g., HIV/AIDS, SARS, and malaria) has received the most attention, emerging diseases have also become a growing problem for plants, livestock, and wild animals (Daszak et al. 2000; Woolhouse 2002; Dobson and Foufopoulos 2001).

A key question is whether these two patterns are related. Owing to the well documented and often positive effects of temperature on pathogen replication, it has often been suggested that current and plausible increases in temperature would enhance transmission and/or exacerbate patterns of pathology (Martens et al. 1995; Bruno et al. 2007; Canto et al. 2009; Harvell et al. 2009). However, warming temperatures can also drive decreases in infections by increasing the mortality rate of pathogens or enhancing host immune function (Paull and Johnson 2011a,b; Studer et al. 2010). In a recent forum in the journal *Ecology*, eminent researchers in the field of disease ecology debated whether local and regional climate conditions could increase the prevalence of infectious diseases. Within this forum, researchers presented arguments along with accompanying data to support increases as well as decreases in the prevalence of particular infectious diseases. In coral, for instance, there appears to be clear evidence that warmer sea temperatures are linked to increased incidence of diseases (e.g., white syndrome, Caribbean yellow band disease (CYBD)), possibly through temperature-mediated suppression of the host immunity (Figure 1; Bruno et al. 2007; Harvell et al. 2009). However, associations between temperature and disease emergence can be obscured by a diversity of cofactors often associated with humans. For example, the spread of malaria into new regions could be curtailed by greater health care resources and active vector-control policies (Hay et al. 2002; Randolph 2009; Chaves and Koenraadt 2010).

Climate-driven changes in infectious disease would likely be a function of both physiological changes of hosts and parasites in response to climate, as well as alterations in the ecological interactions between hosts and parasites (Lafferty 2009). This observation emphasizes the importance of generating detailed knowledge about the specific hosts and pathogens involved in the interaction, how these species are affected by climate change individually and together, and how changes in community structure affect the host–pathogen interaction. These realizations have refocused current efforts toward determining what forms of local and regional climate conditions are likely to influence infection and for what types of diseases we might see increased infections with shifts in temperature or in other climate variables such as precipitation, cloudiness, etc. Importantly, these challenges are not unique to disease ecology, but inherent to research examining species interactions such as pollination, predation, and competition in the face of climate change (Gilman et al. 2010; Tylianakis et al. 2008). In the sections that follow, we provide an overview of the predicted and observed effects of climate change on host–parasite interactions, evaluate the available literature for evidence of climate effects on disease emergence, and discuss future directions that could help expand our understanding of climate-mediated effects on disease.

4.06.2 Challenges Inherent to Detecting a Climate-Driven Signal in Infectious Diseases

Understanding the effects of climate on patterns of disease is complicated by the fact that disease represents the product of interactions between at least two species – a host and a pathogen – each of which may respond differentially to elements of climate such as temperature, precipitation, and the variance associated with these variables. In part, these responses depend on the type of pathogen involved. Pathogens are often classified as microparasites (e.g., viruses, bacteria, fungi) or macroparasites (e.g., helminths, arthropods) that tend to cause disease in hosts under particular conditions. In some cases, other species such as vectors (e.g., mosquitoes, ticks) are also involved in transmission. Importantly, environmental cofactors can influence the progression from infection to disease (Patz et al. 2000). Climate influences the physiology and phenology of most species, resulting in altered species ranges or interactions, changes in host or pathogen abundance, and evolutionary processes if there are local and/or regional changes in climatic conditions (Parmesan 2006; Parmesan and Yohe 2003; Visser and Both 2005). By extension, these changes have been hypothesized to positively affect disease by increasing the pathogen replication rate and shifting species' distributions (Harvell et al. 2009; Ostfeld 2009). Here, we provide an overview of how climate can affect host–pathogen interactions based on theoretical studies as well as field and experiment-based research.

4.06.2.1 Physiology

The metabolic processes of organisms, including hosts, pathogens, and vectors, are intimately linked to variation in temperature. For example, owing to their smaller size, higher metabolism, and faster generation time, pathogen replication rates are expected to increase with temperature, which could positively affect disease dynamics (Rohr et al. 2011). Research across a range of systems supports the argument that higher temperatures tend to enhance pathogen growth (Harvell et al. 2009; Kutz et al. 2005). For example, Harvell et al. (2009) demonstrated a positive correlation between CYBD lesion growth on coral colonies and mean water temperatures. Increased temperatures have also increased the developmental rate of Arctic nematode larvae, a parasite of muskoxen, leading to the completion of development within one season rather than two (Kutz et al. 2005). Collectively, this research suggests that warming could enhance the abundance of certain parasites. However, simultaneous changes in growth and mortality rates in addition to variation in parasite virulence and host susceptibility with temperature make predicting the net effect of temperature on disease dynamics challenging. For example, studies of trematode parasites show that warmer temperatures increase the rates of parasite development, as well as mortality over the range of temperatures (Paull and Johnson 2011b; Studer et al. 2010). Climate-driven physiological changes in hosts and parasites can also impact parasite virulence and host susceptibility to infection (Bruno et al. 2007; Studer et al. 2010; Garrett et al. 2006; Møller 2010), which can lead to either opposing additive or synergistic effects on parasite abundance and host pathology. For instance, Rojas et al. (2005)

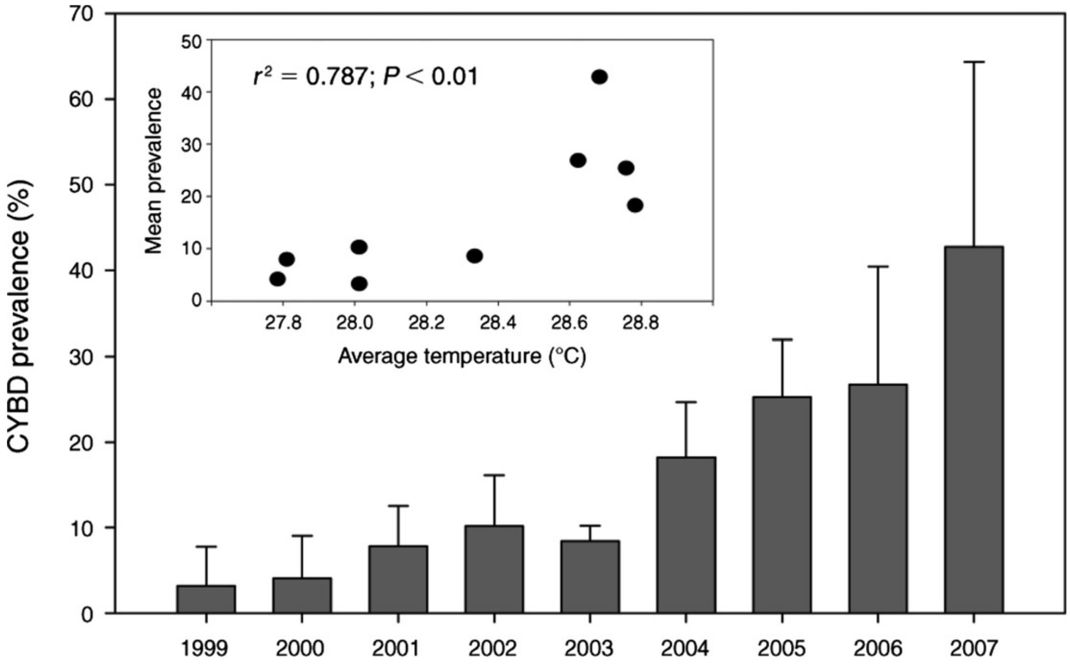

Figure 1 Temporal changes in Caribbean yellow band disease (CYBD). Increase in CYBD prevalence in the Caribbean coral genus *Montastraea* in reefs off the southwest coast of Puerto Rico from 1999 to 2007. The inset shows the positive and significant correlation between the yearly increase in mean prevalence and the average yearly surface water temperature. Harvell, D., S. Altizer, I. M. Cattadori, L. Harrington, and E. Weil, 2009: Climate change and wildlife diseases: When does the host matter the most? *Ecology*, **90**, 912–920. Reprinted with permission by the Ecological Society of America.

demonstrated that the amphibian pathogen *Ambystoma tigrinum* virus (ATV) replicates faster at 26 °C compared to 10 °C in cell culture, yet salamanders failed to develop lethal viral infections at 26 °C due to potentially enhanced immune function at higher temperatures.

4.06.2.2 Range Shifts and Extinctions

Changing temperature and precipitation patterns are leading to shifts in the ranges of hosts, vectors, and pathogens as climatic conditions approach the optima for numerous species (Ostfeld 2009; Purse et al. 2005; Pascual et al. 2009). The climate-mediated movement of pathogens into new regions containing naïve hosts has been a hypothesized mechanism of disease emergence (Ostfeld 2009; Pascual et al. 2009). Bioclimatic models, which use information on the current distribution of species in relation to the current climate to project future shifts in distribution according to the IPCC climate predictions, are frequently implemented to predict how pathogen ranges might shift or expand with plausible changes in local and regional climate (e.g., González et al. 2010). One theoretical argument for the hypothesis that the future climate could lead to range expansion of diseases is that temperature minima are predicted by the IPCC to increase more than the maxima, such that future temperatures may be more likely to increase into the range of temperatures tolerated by pathogens, rather than exceed this range (Ostfeld 2009). For instance, bluetongue virus, a pathogen of ruminants, has expanded its range into 12 European countries since 1998, as a result of milder winter temperatures that favor virus persistence and vector recruitment (Purse et al. 2005). Several bioclimatic models also have demonstrated that the range where climate conditions are suitable for the survival of a wide variety of pathogens and vectors may expand (Bergot et al. 2004; Ogden et al. 2008). However, while climate-driven increases in disease incidence have already been observed along elevational and latitudinal boundaries (Purse et al. 2005; Alonso et al. 2011), this is unlikely to be a universal pattern across all diseases (Lafferty 2009). For instance, several studies point to the possibility of reduced ranges (Randolph and Rogers 2000; Roedder et al. 2010). Such studies demonstrate that although climate affects the total area suitable for pathogen survival (the potential niche), factors such as dispersal limitations, interspecific interactions, and disease control efforts may prevent the pathogen from actually capitalizing on such potential range expansions (the realized niche) (Jeschke and Strayer 2008). Range contractions could also occur if hosts, pathogens, or vectors are dispersal limited, or if their local and regional climate disrupts the interspecific interactions required for disease transmission (Lafferty 2009; Randolph and Rogers 2000).

4.06.2.3 Species Interactions

The combination of climate effects on physiology, phenology, and species distribution ultimately affects species interactions within communities (Gilman et al. 2010). As can be expected, climate-mediated effects on species interactions vary tremendously depending on the system, the type of species interaction (e.g., mutualism, predation, herbivory, competition), and the type of environmental driver (e.g., land use change, nitrogen deposition, CO_2 enrichment, elevated temperature; 24). However, in a review of 688 published studies examining species interactions in the context of environmental change, Tylianakis et al. (2008) found some general patterns including (1) reduced interaction strength in plant–animal mutualisms, (2) changes in the competitive dominant in plant and animal communities, and (3) both positive and negative shifts in the frequency and abundance of predation and herbivory events. Hosts, parasites, and vectors can respond differently to climate, leading to possible shifts in the timing and consequences of host–parasite interactions (Paull and Johnson 2011a,b). For instance, milder winters could limit epidemic chytrid infections of the diatom *Asterionella formosa* by allowing parasites to infect *Asterionella* prior to (rather than during or after) the diatom bloom, effectively limiting population growth of both the host and the parasite [(Ibelings et al. 2011) for an example involving algal–grazer interactions see also Winder and Schindler (2004)]. Similarly, a long-term study of barn swallow parasites found that the 'relative capture date' of louse flies relative to adult barn swallows grew progressively earlier over the decades, suggesting that louse fly phenology changes are stronger than those of its swallow host (Møller 2010). Such changes in the timing of host–parasite interactions could have consequences for disease dynamics and host pathology, highlighting the importance of accounting for climate-driven changes to interspecific interactions when predicting future disease dynamics.

4.06.3 A Retrospective Literature Analysis of Climate Change and Disease

In light of the potential complexity surrounding host–parasite interaction outcomes in response to climate, a valuable tool for assessing the state of the research field and the observed empirical results is through an examination of published studies. Given that, in some regions, observations of climate have been recorded for at least the last half century (IPCC 2007), a retrospective evaluation of available research is long overdue. Recent literature reviews suggest that interest in the effects of climate on disease dynamics is increasing within the academic community (Rohr et al. 2011; Paull and Johnson 2011a,b). To date, however, the idea that contemporary changes in climate have led to broadly observed changes in infection patterns has not been empirically tested using published studies. If there is evidence for an increased focus on climate-mediated effects on disease dynamics, this raises an important question: Does the increase in studies on climate–disease interactions reflect a growing body of evidence linking shifts in climate to patterns of disease? While experiments have highlighted the potential mechanisms underlying climate-mediated effects on disease and theoretical studies have predicted disease dynamics in the face of changes in local and regional climatic conditions, whether the observed changes in climate over the past several decades have positively contributed to disease emergence remains largely conjectural. Few studies have synthesized the literature to assess the evidence for an association between climate and disease.

4.06.3.1 Assessing Interest in Climate–Disease Interactions

We used the literature survey methods of Ward and Lafferty (2004) to address whether the frequency of publications examining climate-driven effects on infectious diseases has increased over the past four decades after accounting for research effort (normalized by the total number of publications on climate) and for temporal autocorrelation (see Johnson and Paull 2011). We developed title-specific search strings using the literature search engine ISI Web of Science, which included separate terms related to either disease (see Johnson and Paull 2011) or climate change {TI=[climate* and (change or shift* or disrupt* or anomal* or variation or variability or warm*) or (global and warming) or [extreme and (event* or drought* or flood*)] or (el and nino) or (la and nina)]}. We identified 249 articles published between 1970 and 2010 that included climate and disease related search terms in the title and 9208 articles published between 1990 and 2010 that included these terms in the title or the abstract. Our retrospective evaluation indicated that, prior to 1990, very little research addressed the linkage between climate and disease emergence. In fact, no articles satisfied the joint search criteria used in this chapter during the period from 1970 to 1989 (e.g., none of the articles on climate change also included the disease search terms in the title). After 1990, however, both the total and the proportion of climate change research focused on disease have increased steadily and significantly (**Figure 2**). We used Generalized Additive Mixed Models (R package mcgv) to test for a significant effect of year, along with an information theoretic approach to evaluate the fit of different autoregressive moving average (ARMA) terms (p and q) across different lags to account for temporal autocorrelation (Johnson and Paull 2011). After accounting for the general increase in research (as indicated by the total number of publications on climate change), we observed an approximate doubling in publications over the past 20 years (from $<1\%$ in 1990 to $>2\%$ in 2010 for title-based searches). The same pattern was also observed using article abstracts for the period between 1990 and 2010, although the increase was generally linear (e.g., no smoothing term was needed). Thus, despite the complexity inherent to understanding climate-mediated effects on disease, these results suggest that interest in climate-mediated effects on disease has increased significantly and substantially over time.

4.06.3.2 Assessing Evidence That Climate Shifts Affect Patterns of Disease

We narrowed our literature search to long-term field studies (≥ 5 years) that examined the effects of climate on disease within wildlife populations. We opted to exclude human disease studies because several confounding variables such as socioeconomic factors and prevention strategies obscure our ability to assess climate–disease linkages, and several interesting reviews have addressed this topic in greater detail (Randolph 2002; Reiter 2001; Zell et al. 2008). We identified only 11 publications from over 477 possible articles (**Table 1**), and of these 11, 3 reported results from multiple pathogens or parasites. Thus, there were 17 total reports of climate-mediated effects on disease from the 11 studies. Across the 11 studies, there were 10 reports (59%) of increased pathogen or disease incidence with temperature increases and precipitation changes (**Table 1**). By contrast, there were three reports (18%) of decreased pathogen or disease incidence with temperature increases and precipitation changes and four reports (23%) of no change. While the

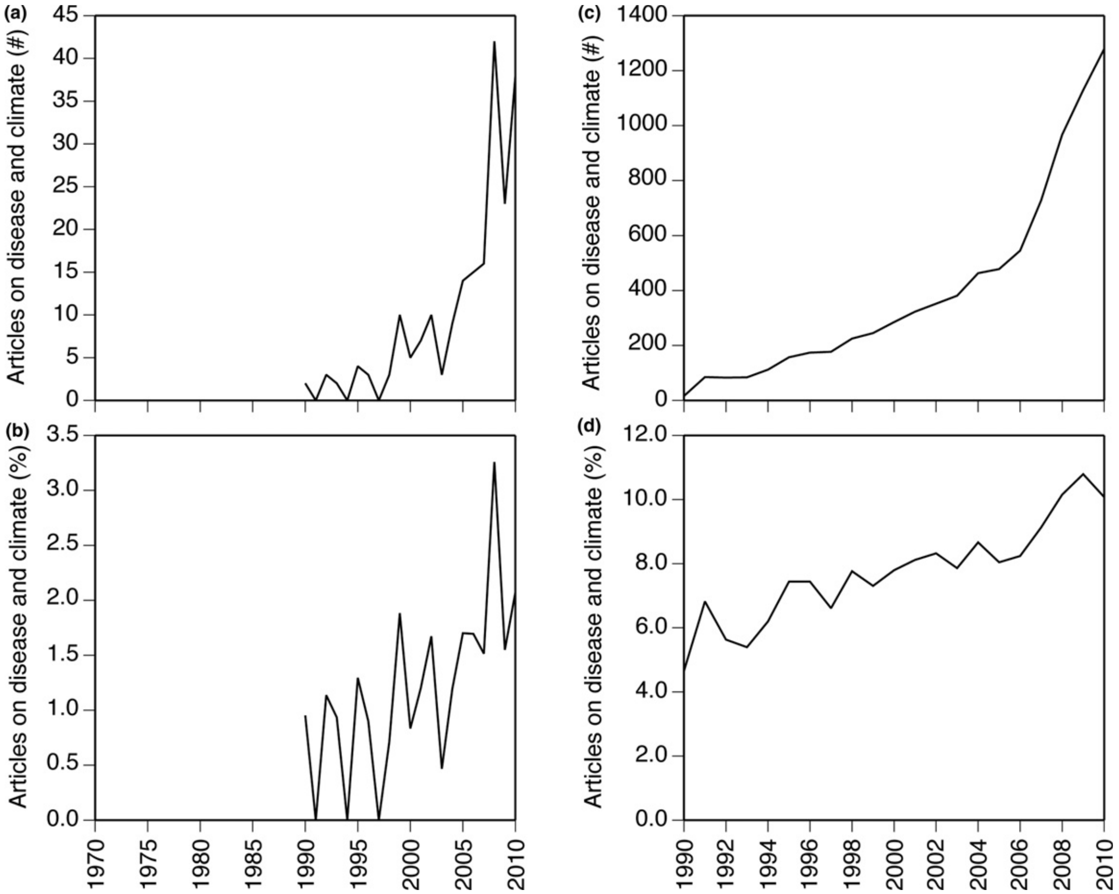

Figure 2 Long-term publication trends for climate-driven effects on infectious diseases. (a) Number of articles with disease in title (1970–10); best model did not need a smoothing term, but included a moving average term of 1 ($p = 0$, $q = 1$); R^2 adj = 0.87, $n = 41$; s(YEAR): edf = 1, $P < 0.00001$. (b) Proportion of articles with disease in title (1970–2010); best model included a smoothing term and a lag of 2 years ($p = q = 2$). R^2 adj = 0.72, $n = 41$; s(YEAR): edf = 3.32, $P < 0.00001$. (c) Number of articles with disease in abstract or title (1990–10); best model included a smoothing term, an autoregressive term, and a moving average term of 2 ($p = 2$, $q = 1$); ($p = 0$, $q = 2$); R^2 adj = 0.99, $n = 21$; s(YEAR): edf = 6.49, $P < 0.00001$. (d) Proportion of articles with disease in abstract or title (1990–2010); best model included no smoothing term and no autoregressive or moving average terms ($p = q = 0$); R^2 adj = 0.84, $n = 21$; s(YEAR): edf = 1, $P < 0.00001$.

majority of the published research was suggestive of a positive linkage between climate and disease, the mechanisms underlying these associations varied across systems. For vector-borne pathogens, the most commonly cited mechanism was climate-mediated effects on vector abundance (Møller 2010; Stenseth et al. 2006). Specifically, mild winters and wet years were reported to enhance survival and reproduction of vectors, potentially contributing to greater disease risk. Climate also had a positive direct effect on some pathogens. Increasing temperatures enhanced the growth or replication rate of the pathogen in several studies (Bruno et al. 2007; Karvonen et al. 2010). However, increased temperature also decreased the prevalence of other pathogens due to a shift away from optimal growing conditions (Karvonen et al. 2010) or led to greater mortality rates when outside of the host (Ibelings et al. 2011). There was also evidence that climate altered host physiology. For instance, increasing temperatures were associated with immunosuppression of the host, which resulted in greater disease incidence (Bruno et al. 2007; Harvell et al. 2009).

Collectively, these results suggest that there is general support for a positive association between temperature and precipitation change for diseases caused by a variety of parasite types (e.g., viruses, bacteria, fungi, protozoans, nematodes), within a diverse range of host taxa (e.g., invertebrates, fish, birds, mammals), and ecosystems (e.g., freshwater, marine, terrestrial), but the mechanisms underlying these associations are varied and far from universal. Several studies suggested that positive associations between temperature and coral diseases may be the result of temperature-driven reductions in host immune responses (Bruno et al. 2007; Harvell et al. 2009). By contrast, associations between climate and diseases of endotherms (e.g., birds and mammals) were more often thought to be driven by changes in parasite or vector populations (Møller 2010; Hudson et al. 2006). Still other studies indicate the potential for more complex relationships between climate and disease risk, governed by the timing of host infection (Ibelings et al. 2011).

It is important to note that surprisingly few long-term studies have been conducted (and published) based on wildlife populations. Although a positive association between changes in temperature and precipitation and wildlife diseases was supported by this analysis, the paucity of research limits our

Table 1 Summary of multi year field studies examining the effects of climate change variables on disease dynamics in wildlife hosts. For each study, the effects of climate change on disease dynamics are summarized as either positive, negative, or no change. For studies that examined multiple pathogens, the results are summarized across all the pathogens

				Association with the variable		
Host	*Disease or pathogen*	*Location*	*Climate variable(s)*	*Positive*	*Negative*	*No change*

ability to generalize the observed trend across the diversity of taxa that are likely to be influenced by any changes in local and regional climate. As in any survey of the literature, a significant concern is publication bias (Gates 2002). Interestingly, studies that reported negative or no associations with one disease were often accompanied by results that showed a positive association with changes in temperature and precipitation for a different pathogen. While it is difficult to determine whether publication bias exists in the literature examining climate-mediated effects on disease, particularly when so few studies have been published, the existing experimental literature suggests that climate has the potential to influence disease in a variety of positive as well as negative directions. Thus, we suspect that publication bias toward reporting increases in disease with temperature increases and precipitation changes may be a contributing factor in our survey results. Alternatively, however, given the many concurrent factors that can influence infection alongside climate, it may be that detecting climate-based effects on disease in naturally occurring populations is frequently obscured by concurrent changes in other driver variables. Taken together, these two observations underscore the need for more long-term studies of disease and climate that incorporate multiple pathogens and host species to provide a more robust test of the hypothesized role of climate shifts in disease emergence.

4.06.4 Future Research Directions

Interest in the role of climate in disease emergence has grown considerably over the past two decades. Surprisingly, however, relatively few field studies have quantitatively evaluated the role of shifts in temperature, precipitation, or their variability in affecting diseases of wildlife. For the few studies that have examined the responses of host–pathogen interactions in wildlife, there was a general trend for increased pathogen prevalence with temperature increases and precipitation changes. However, the paucity of data on wildlife pathogens limits the generalizations that can be made and presents an important quandary: Why are there relatively few empirical studies examining the linkage between climate and disease emergence in wildlife populations, particularly given a nearly >40-year history of climate data? There could be a number of explanations. It is possible that the data simply do not exist at this time. Although researchers identified the threat of changes in local and regional climate decades ago, there could be too few long-term data sets on disease or pathogen prevalence in wildlife populations to make meaningful assessments of linkages between climate and disease emergence (e.g., Johnson et al. 2009). It is also possible that long-term data sets exist, but the results do not support the hypothesis that climate change mediates disease emergence. Consequently, researchers could be less likely to publish these results, which are counter to most theoretical predictions (Ioannidis 2005; Rosenthal 1979). Lastly, the complexity inherent to host–pathogen systems coupled with the multifaceted impacts of climate on these interactions could present a significant research barrier, hindering the ability of researchers to detect climate-mediated effects even when present. Below, we suggest future directions that could help expand our understanding of climate-mediated effects on disease and overcome some of these potential challenges.

4.06.4.1 Greater Emphasis on Long-Term Data

An obvious obstacle to assessing the effects of climate on infectious diseases is the lack of long-term data. As experimental and theoretical approaches continue to advance our understanding of the potential mechanisms that could drive changes in disease incidence with climate, it is imperative that long-term field studies are implemented to test these mechanisms in wildlife and the human disease systems. For instance, the U.S. National Science Foundation has sponsored the formation of the National Ecological Observatory Network (NEON; www.neoninc.org/), which is specifically designed to assess the impacts of climate on ecological systems, including infectious diseases at sites across the United States. By establishing disease monitoring programs at sites that span a diversity of ecosystems and component species, there is the opportunity to gain broad insights into the role that climate plays in disease dynamics. For example, similarities and differences in disease outcomes can be compared across different host–pathogen systems or for particular host–pathogen systems that are embedded within different environmental contexts. This information may help to address potential publication bias in the literature by generating additional data sets for publication and examining a diversity of host–pathogen systems. As such, this research has the potential to provide comprehensive tests of the hypothesized role of climate in disease emergence across host species and pathogen types.

4.06.4.2 Trait-Based Approaches and Risk Matrices

The complexity of many disease systems combined with uncertainties in climate predictions pose significant challenges for predicting which diseases could respond positively or negatively to changes in local and regional climate. Climate can alter disease risk by affecting host vulnerability to infection (e.g., via changes to host resistance or tolerance), changing parasite or vector populations (e.g., via replication, infectivity, or habitat availability), or shifting the timing or location of host–parasite interactions (e.g., via phenological or range shifts). Some hosts, such as corals may be particularly sensitive to warm temperatures at which their associated pathogens are still able to thrive (Harvell et al. 2009). On the opposite end of the spectrum are certain fungal pathogens that are adapted to cooler temperatures and may decline with warmer temperatures (Sturrock et al. 2011). Trait-based approaches to understanding host immunity and/or disease risk are gaining increased attention (Cronin et al. 2010; Johnson et al. 2012) and may prove useful in developing a 'risk matrix' of climate impacts on disease (Rohr et al. 2011). Such trait-based approaches to thermal sensitivity of hosts and parasites could also be combined with knowledge of species' ranges and habitat quality to further narrow our predictions of where climate-driven increases in disease risk for a given species are the greatest threat. For instance, hosts living at the limits of their ranges, or in habitats that are experiencing other forms of environmental degradation may be particularly sensitive to alterations in local and regional climate (Portner and Farrell 2008), making them more susceptible to disease.

4.06.4.3 New Analytical Techniques to Address Climate–Community Interactions

A key gap in our understanding of the ecological effects of climate involves identifying how shifting temperatures and rainfall could influence species interactions and community dynamics (Gilman et al. 2010). Because infectious diseases are governed by intra- and interspecific transmission events, understanding how climate affects such interactions is a critical component of determining how disease risk may be altered (Rohr et al. 2011; Paull and Johnson 2011a,b). Individual species can have different physiological, phenological, and distributional responses to changing temperatures and precipitation, which would shift the character and timing of interspecific interactions, as well as the suite of interacting species (Walther et al. 2002; Parmesan 2006; Parmesan et al. 2011; Parmesan and Yohe 2003; Post et al. 2009; Hoegh-Guldberg and Bruno 2010; Woodward et al. 2010). Few studies, however, have considered how these phenomena will ultimately influence disease.

Improving our understanding of how climate could alter host–parasite interactions will require a more nuanced empirical understanding of the climate-dependence of organismal physiology, and a better incorporation of these parameters into simplified host–parasite models and community modules (Gilman et al. 2010; Fuller et al. 2010; Helmuth et al. 2010; Helmuth et al. 2011). A simplifying assumption made in numerous climate-disease studies is that organismal growth and development has a positive linear relationship with temperature (Rohr et al. 2011). In reality, however, increases in temperature enhance the performance of organisms up to a critical threshold after which performance declines (Bruno et al. 2007; Rohr et al. 2011; Codeco et al. 2008; Angilletta 2009). Determining how the shape and range of these thermal performance curves vary across species will be important for assessing whether climatic conditions could increase or reduce the growth and mortality rates or stress experienced by hosts, vectors, and parasites (Rohr et al. 2011). Precipitation is a similarly important driver of organismal physiology, governing the timing of reproduction, as well as growth and development in many species (Parmesan 2006). If hosts, vectors, and parasites respond differently to changes in temperature and precipitation, this can lead to shifts in the timing of host–parasite interactions, transmission rates, and changes in relative abundance (Ostfeld 2009; Møller 2010; Purse et al. 2005; Ibelings et al. 2011). Thus, models incorporating these physiological changes in all organisms involved in the transmission cycle will expand our ability to predict climate-driven changes to select well parameterized disease systems (Rohr et al. 2011; Paull and Johnson 2011a,b).

Limitations on the ability to obtain parameter estimates in many disease systems will make incorporating all of these physiological responses challenging, highlighting the need to develop simplifying assumptions that do not obscure the most important drivers of change. Thus, using theoretical 'community modules' to test which of these physiological responses are likely to have the largest effect will be an important step toward determining which parameters should be included in the model. Gilman et al. (2010) suggest some generalized ecological community modules that could be adapted to incorporate disease systems more specifically. For example, modeling the effects of climate on transmission between two hosts and a vector or between intermediate and definitive hosts could offer insight into which drivers have the strongest effect on disease transmission in those systems. These effects could then be scaled up to explore disease dynamics within larger communities that are influenced by climate shifts.

4.06.4.4 Greater Synthesis

A growing body of evidence shows that local and regional climatic conditions affects the physiology and phenology of most species, leading to effects on species ranges, interactions, and evolutionary processes (Parmesan 2006; Parmesan amd Yohe 2003; Visser and Both 2005). The need to synthesize this information into a cohesive management framework has inspired recent attempts to develop vulnerability assessments for the responses of species and ecosystems to climate (Heikkinen et al. 2010; Huey et al. 2009; Dawson et al. 2011). Such assessments can provide crucial information about where management efforts may be most efficiently allocated. These analyses have predominately been completed for free-living species, yet parasites and pathogens also respond in nonlinear and idiosyncratic ways to climate (Rohr et al. 2011; Roy et al. 2004). Although the diversity and complexity of host–pathogen interactions presents a significant challenge to developing vulnerability assessments, a greater emphasis on conducting comparisons across host–pathogen systems that differ in key ecological (e.g., environmental backgrounds) and epidemiological (e.g., transmission dynamics) parameters will help to provide general insights into the link between climate change and disease emergence. Efforts to adapt these analyses to assess the infectious diseases that are most likely to emerge as a result of climate change will benefit managers seeking to mitigate climate-driven changes to diseases of humans, plants, and wildlife. However, our ability to meaningfully implement vulnerability assessments is contingent on the initiation of more long-term research on host–pathogen responses to climate.

4.06.5 Conclusion

The debate continues over the effects of climate on the distribution and severity of diseases (Wilson 2009). It is clear that climate has both direct and indirect effects on disease incidence by influencing the environmental context in which host–pathogen interactions are embedded. However, simple generalizations about whether climate has played a role in disease emergence are precluded by the complexity associated with host–pathogen interactions within communities, the confounding influence of multiple and concurrent environmental change drivers, and the lack of published long-term studies. To expand our understanding of climate-mediated effects on disease, there is a need to integrate empirical and theoretical research across multiple scales (e.g., organism physiology to interacting communities), which will require greater collaborative efforts involving researchers with diverse expertise.

Glossary

Climate extreme A statistically rare or unusual occurrence, with respect to the historic distribution of climate parameters of a system, of one or a combination of climate parameter values (e.g., mean, minimum or maximum temperature); examples include heat waves, severe drought, and periods of heavy rainfall. A climate extreme differs from a weather extreme in that it captures average climate conditions over longer periods of time, whereas weather extremes refer to unusual occurrences in precipitation or temperature on a day-to-day basis.

Extreme climatic event An episode or occurrence in which a statistically rare or unusual climatic period alters ecosystem structure and/or function well outside the bounds of what is considered typical or normal variability.

4.07.1 Introduction

Human activities are changing the climate system (IPCC 2007; Kabat et al. 2004; NRC 2005), including changes in the composition of the earth's atmosphere, through an increase in greenhouse gas emissions resulting from energy production and biomass burning, aerosol emissions, and land use change. Although, there remains uncertainty as to the rate and magnitude of changes in climate statistics, it is clear that human-caused changes are already occurring and will continue over the rest of the current century. Hence, there is a pressing need to better understand and predict the consequences of possible climate changes on ecological systems, even if the specific projections have not been shown to have regional predictability (NRC 2001; Lucier et al. 2006; Pielke et al. 2012).

The possible change of climate extremes, such as heat waves, periods of heavy rainfall (and associated floods), and severe drought, is now recognized as one of the most important aspects of concern with respect to climate by the broader scientific community (Solomon et al. 2007; Jentsch et al. 2007; Jentsch and Beierkuhnlein 2008; Smith 2011a,b; IPCC 2012). This is, in part, because climate extremes are expected to have large and widespread impacts on both managed and natural ecosystems, and the services they provide (Easterling et al. 2000; Parmesan et al. 2000; Ciais et al. 2005; Smith 2011b), as well as profound economic costs, and significant consequences for human welfare (Karl and Easterling 1999; Easterling et al. 2000; Beniston and Stephenson 2004; Garcia-Herrara et al. 2010). Changes in climate means and variability could increase both the probability of occurrence and magnitude of these extremes in the future (Mearns et al. 1984; Houghton et al. 2001; Solomon et al. 2007). Thus, climate extremes will continue to figure prominently as a diverse set of drivers of ecological dynamics in the coming decades.

In this chapter, I first provide some historical context for the study of climate extremes, followed by an overview of the ecological consequences of climate extremes, and a framework for assessing their impacts on ecosystem function and services. I conclude by discussing future research needed for advancing our understanding of the effects of climate extremes on ecosystems.

4.07.2 The Emerging Field of Climate Extremes Research

The ecological consequences of extremes or extreme events, particularly those associated with climate (e.g., floods, drought, hurricanes), have long been of interest to ecologists, with the ecological responses to climate (weather) extremes (droughts, floods, windstorms, etc.) often studied within the field of disturbance ecology (Pickett and White 1986). Evolutionary ecologists have similarly recognized the role of climate extremes as potential drivers of selection, trait fixation, and speciation (Gutschick and BassiriRad 2003; Combes 2008). Despite the long-standing recognition of their ecological importance, the study of climate extremes, as a threat to

http://dx.doi.org/10.1016/B978-0-12-384703-4.00409-3

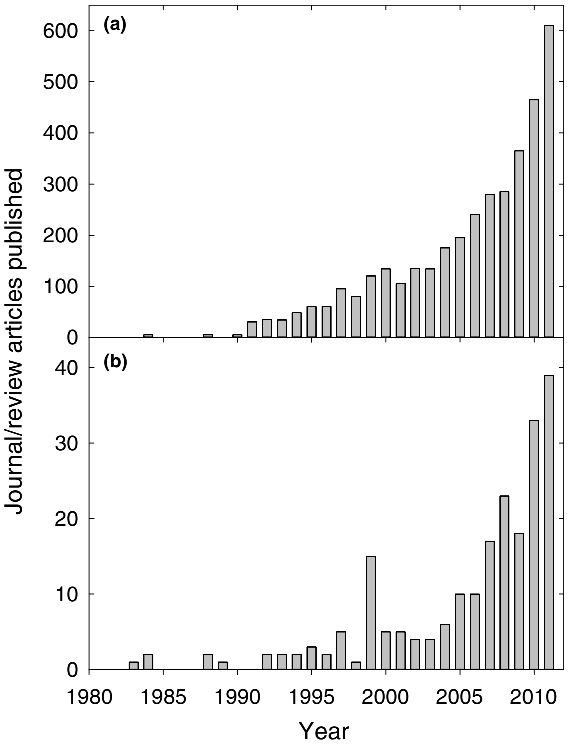

Figure 1 Results from a Web of Science search by topic (a, 3767 records) and by title (b, 216 records) for the terms "climate extreme*," "extreme climat(e/ic)," "weather extreme*," and "extreme weather." Search results were further refined by including only journal and review papers within the categories ecology, environmental sciences, or water resources. The latter filters were used to exclude climatological and meteorological papers in order to emphasize trends in ecological and environmental research. The time period for the search was "all years in database." Only the last 30 years are shown for simplicity, as very few records occurred before this time period.

ecosystem function and services, has only recently gained momentum in the field of ecology.

To illustrate this recent increase in interest, a Web of Science search was conducted within ecological and environmental journals on the terms 'climate extreme(s),' 'extreme climat(e/ic),' 'weather extreme(s),' and 'extreme weather' – terms which have now become part of the lexicon of climate (Figure 1). The goal of this search was to exclude climatological and meteorological studies and distinguish between the more traditional ecological research papers focused on specific types of climatic events (such as floods, droughts) from papers published that include a broader conceptualization of climate extremes within the context of climate. The search was first conducted more generally to evaluate trends in the topical use of these terms anywhere in published papers (Figure 1(a)). The search was then modified to include only those papers with these terms in the title (Figure 1(b)), in order to identify trends in published works specifically focused on climate extremes.

The search revealed that although use of 'climate extremes' (and associated terms) extends back over 60 years in the Web of Science database, more general interest and recognition of climate extremes only began in earnest in the early 1990s, and since the mid-2000s has increased exponentially (Figure 1). Mirroring this more general interest in climate extremes, the trends in papers published that are primarily focused on climate extremes, as evidenced by use of the terms in the title (Figure 1(b)), illustrates how young and emergent this field is within the ecological community. For example, there was an average of three papers per year published with climate extremes in the title in the 1990s, but this increased 10-fold to 39 in 2011. Interestingly, this number is still only approximately 10% of the 380 papers in 2011 that more generally included the term climate extremes in the body of the paper (Figure 1(a)). This suggests that recognition of the importance of climate extremes far outpaces studies specifically focused on this well-recognized aspect of climate.

4.07.3 Ecosystem Impacts of Climate Extremes

The recent increase in recognition of the ecological importance of climate extremes (Easterling et al. 2000; Jentsch and Beierkuhnlein 2008) has led to a number of studies focused on understanding organismal to ecosystem impacts of climate extremes (Jentsch et al. 2011). Smith (2011b) reviewed some of these studies and found that the impacts of climate extremes on ecosystems can be quite variable. For example, a period of climate extremity, such as a heat wave or severe drought, can result in widespread mortality of key populations or species (Weaver 1968; Breshears et al. 2005; Bigler et al. 2006, 2007; Giltin et al. 2006; Miriti et al. 2007; Thibault and Brown 2008), dramatic alterations in community structure (species diversity, abundance of species), and ecosystem functions (MacGillivray et al. 1995; White et al. 2000; Haddad et al. 2002; Ciais et al. 2005; Mueller et al. 2005; Evans et al. 2011; Kreyling et al. 2011), increased vulnerability to invasion by exotic species (Jimenez et al. 2011), and landscape-scale shifts in ecotone boundaries (Allen and Breshears 1998). However, the effects of these climate extremes also can be quite limited and/or merely transient, with only negligible ecosystem impacts (Van Peer et al. 2001, 2004; Marchand et al. 2005, 2006a,b; Milbau et al. 2005; Bokhorst et al. 2008; Kreyling et al. 2008; Arnone et al. 2011; Jentsch et al. 2011).

This apparent variability among ecosystems, in their sensitivity to climate extremes, raises important questions about the determinants of ecosystem vulnerability to these periods of climate extremity and our ability to assess possible ecosystem responses to alterations in climate extremes. Several questions arise including: Are there characteristics or factors that make ecosystems more or less vulnerable to climate extremes? Are there thresholds of ecosystem response to periods of climate extremity? How extreme does a climate event, such as a severe drought, flood or heat wave, need to be to push systems across these thresholds or evoke large ecological responses?

Addressing these and related questions is particularly challenging due to the inherent context dependency of climate extremes (Smith 2011b). This context dependence arises in two ways. By definition, a climate extreme represents the tails of the distribution of a climatic parameter (e.g., mean temperature) or a combination of climate parameters (Figure 2), as in the case of severe drought, which involves low precipitation amounts and high temperatures (Easterling et al. 2000; Jentsch et al. 2007). Thus, statistical rarity is a key feature of climate extremes, and accordingly identifying what constitutes 'rare' requires extensive

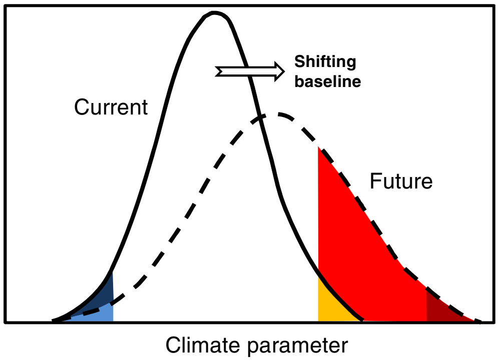

Figure 2 Climate extremes (e.g., defined as those with $\leq$5% statistical probability of occurrence; dark blue–yellow portions of the "current" climate curve, light blue–dark red portions of the "future" climate curve) could become more frequent and intense with changes in climate means and/or alterations in the distribution of climate variables (red shaded area). A similar shift also could occur to the left in the above figure, but only the right shift is shown for simplicity. With changes in climate means (represented by the shift in the future curve to the right) and variability (represented by a widening in the future distribution), the climatic baseline would shift (arrow), and consequently far fewer climate conditions would be deemed extreme based on the statistical definition of rarity (dark red shaded area), even though organisms in the system would be experiencing many more periods of climatic extremity (red + dark red shaded areas). Establishment of a fixed and standardized climatic baseline for ecological studies will improve our ability to interpret how climate extremes may be altered and will impact ecosystems with changes in climate statistics. From Smith, M. D., 2011a: The ecological role of climate extremes: current understanding and future prospects. *J. Ecol.*, **99,** 651–655.

knowledge of the climate record, which is often lacking for many ecosystems. However, what constitutes 'extreme' depends not only on the climate record but also what the system has experienced previously – both in the short-term and the long-term. In the short-term, a severe drought that follows several years of below average precipitation, for example, may have different impacts than one that occurs right after a wet period. When considering climate over the long-term, an ecosystem with high interannual variability may respond differently to a climate extreme than one that has low variability, for example. Thus, the 'extremeness' of a climate event and the consequent vulnerability of the system to that event will depend not only on whether a climate extreme is rare from a statistical sense but also how those conditions relate to both long-term and short-term climatic variability experienced by the ecosystem. The expectation is that, if the climate extreme alters environmental conditions well outside the bounds typically experienced by a system, then an 'extreme' (statistically unusual) ecosystem response will result. In other words, a climate extreme that causes widespread mortality of species, for example, as opposed to one that just merely alters physiology of individuals. Without knowledge of both aspects of context dependence, it is difficult to determine whether variability in the vulnerability of ecosystems to climate extremes is due to some ecosystems having characteristics that make them particularly resistant (or susceptible) to a climate extreme versus the possibility that an ecosystem did not experience truly extreme climate conditions.

Thus, as I have argued previously (Smith 2011b), in order to advance our understanding of the impacts of climate extremes on ecosystems and what factors underlie ecosystem vulnerability to climate extremes, we must be able to identify when climate conditions are extreme, determine when extreme ecosystem responses occur, and most importantly, be able to attribute the climate extreme as the driver of an extreme ecosystem response. Smith (2011b) refers to the latter as an extreme climatic event (ECE). The identification and attribution of each of these requires that there are clear definitions of what constitutes a climate extreme, an extreme ecological response, and an ECE.

4.07.4 Definitions of Climate Extremes, Extreme Ecological Responses, and ECEs

Defining a climate extreme is much more straightforward than defining what constitutes an extreme ecological response (Smith 2011a). As indicated above, definitions of climate extremes have generally been based on the statistical distribution of a climate variable for any system (Figure 2), with extremes represented by the tails of distribution of a particular climate parameter (e.g., mean, maximum, minimum temperature) or combination of parameters (as in the case of a drought). A climate extreme differs from a weather extreme in that, it captures average climate conditions over longer periods of time, whereas weather extremes refer to unusual occurrences in precipitation or temperature on a day-to-day basis. The expectation with any change in climate means and/or variability is that climate extremes would become more frequent and intense in the future (Figure 2; Meehl et al. 2000). Due to the statistical nature of the definition, this increase in frequency and intensity must be predicated on a fixed frame of reference or climatic baseline (e.g., the historic climate record for a site). For example, a shift in mean temperatures toward warmer conditions would result in a greater number of high temperature extremes based on the current statistical distribution (red shaded area, Figure 2), particularly if variability around the mean also is increased. However, if the climatic baseline is allowed to shift, as would occur with increases in the means and/or alterations in the distributions of climate variables, then substantially fewer climate conditions would be deemed extreme based on, for example, a $\leq$5% statistical probability of occurrence (dark red shaded area, Figure 2). This statistically based outcome would occur even though periods of climate extremity would actually be much more common from the perspective of the organisms in the system (e.g., red + dark red shaded areas, Figure 2) relative to the conditions they had previously experienced. In other words, to be ecologically meaningful, the statistical attributes of the long-term climate that the biota have been experiencing historically (e.g., prior to changing climate statistics) should be similar to those used to determine extremity. Therefore, there is a clear need to establish relevant or fixed climatic baselines for identifying climate extremes (Smith 2011a). An example of a fixed baseline that has proven to be invaluable is the ca. 280 ppm pre-industrial atmospheric CO_2 concentration for studies of the impacts of increases in atmospheric CO_2 on ecosystems. For climate extremes research, system-specific climatic baselines would provide the necessary benchmarks for assessing how the frequency and magnitude of extremes may change with current and future scenarios of climate, and allow for the determination of when a period of climatic extremity has occurred for a particular ecosystem.

In contrast to climate extremes, defining an extreme ecological response is more difficult (Gutschick and Bassirirad 2003), as it depends on both the ecological system in question and the timescale considered. For example, the drivers and the magnitude of a statistically extreme response for a desert grassland has the potential to be very different than that for a tropical forest. Moreover, the extremity of a response for a particular system may change considerably if one considers the 20 years of historic variability versus a millennial scale paleo-record for the same site. From an ecological response perspective, Gutschick and BassiriRad (2003) defined an extreme event (climatic or otherwise), as one in which the ability of an organism or population to acclimate is substantially exceeded, with often persistent effects after the event, resulting in longer-term impacts on fitness. The limitation of this definition is that the most extreme ecological response (e.g., left tail of the distribution, **Figure 3**) is mortality of individuals or entire populations. However, depending on the role and abundance of the species impacted, such responses may or may not result in changes at the community or ecosystem level that can be distinguished from background variability. For example, mortality of individuals in a population, or even entire populations within a community, may have negligible impacts beyond the particular population or populations affected, if the impacted species are rare overall or have minimal roles in key ecosystem processes.

Smith (2011b) argued that for an ecological response to be considered extreme it should include responses beyond the individual or population level, including substantial changes in community composition and structure caused by the reordering of key or common species in the community, widespread species loss, and/or invasion by novel species, with subsequent large and potentially persistent effects on ecosystem structure and function (**Figure 4**, Smith et al. 2009). While mortality of individuals and/or populations and associated changes in fitness may underlie these higher-level responses, particularly if, for example, dominant species are impacted (e.g., Allen and Breshears 1998), an extreme ecological response should be one in which ecosystem structure and/or function is altered well outside the bounds of what is considered typical or normal variability and cascades across multiple hierarchical levels (e.g., population, community, and ecosystem). As with climate extremes, characterizing the distribution of ecological responses for an ecosystem is critical for determining when an extreme ecological response occurs. However, this characterization will be a significant challenge for many ecosystems as many ecological studies are of short duration. The inherent difficulty of describing the potential range of ecological responses of any ecosystem emphasizes the value of long-term studies of a broad range of ecosystems, which can provide the necessary context for interpreting ecosystem responses and a baseline for evaluating extremeness of ecological responses (Callahan 1984).

Not all climate extremes result in extreme ecological responses as defined above (**Figure 4**, Smith 2011b). However, being able to attribute a period of climate extremity as the driver of an extreme ecological response is critical for determining what factors may contribute to differential vulnerability of ecosystems to climate extremes. Thus, although the term 'extreme climate (or climatic) event' is often used interchangeably with climate extremes in the literature, the term 'extreme climatic event' should only be used in the case where an extreme ecological response results from a climate extreme. Given this, Smith (2011b) defined an ECE as an episode or occurrence in which a statistically rare or unusual climatic period results in an alteration in ecosystem structure and/or function well outside the bounds of what is considered typical or normal variability (**Figure 4**). The use of 'event' denotes the nominal short duration of the occurrence (discreteness) relative to the magnitude of its effects (Jentsch et al. 2007). Moreover, this definition emphasizes the need to define ECEs synthetically, from both the driver (occurrence) and response (effect) perspectives (**Figure 3**). Because extreme ecological responses are characterized by profound alterations in ecosystem function and structure that are driven by changes in species abundances, loss of key species and/or invasion by new species with different functional traits, ECE's are likely to result in periods of prolonged ecosystem recovery, significant hysteresis, and/or persistent state changes (**Figure 4**; e.g., Allen

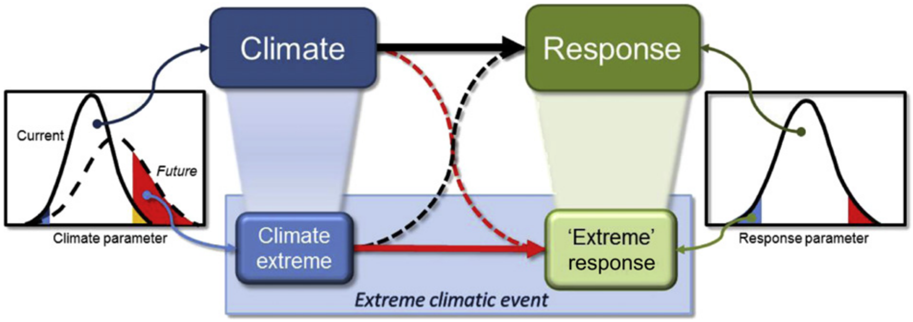

Figure 3 Changes in climate means and variability could result in a response that is well within the range of variability for a system (solid black arrow) or one that is extreme (represented by tails of the distribution on the right, dashed red arrow). Similarly, climate extremes (represented by tails of the distribution on the left) may (solid red arrow) or may not (dashed black arrow) result in an ecological response that is outside the typical or normal range of variability for a system. An extreme climatic event (ECE) is defined synthetically as the case in which an extreme ecological response can be directly attributed to a period of climate extremity. From Smith, M. D., 2011b: An ecological perspective on extreme climatic events: a synthetic definition and framework to guide future research. *J. Ecol.*, **99,** 656–663.

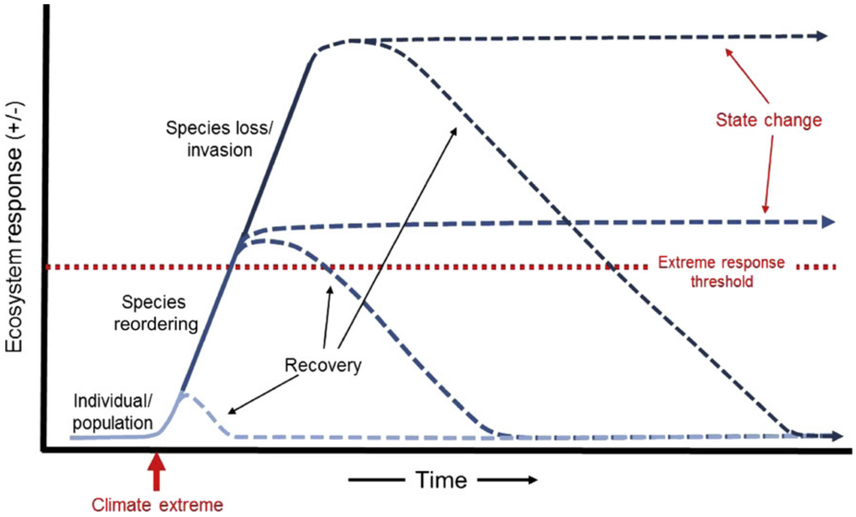

Figure 4 A framework for assessing ecosystem responses to climate extremes. A period of climate extremity that primarily affects individual-level responses (physiology, growth, fitness) of particular organisms–populations will have a smaller effect (positive or negative) on ecosystem processes (e.g., productivity, nutrient cycling) than one that results in large shifts in species abundances (species reordering), or in local extinction of species or invasion by others. An extreme climatic event is an episode or occurrence in which a period of statistical climate extremity alters ecosystem structure and/or function outside the bounds of what is considered typical or normal variability, as a consequence of crossing an extreme response threshold (dotted red line) in which individual-level effects cascade to higher hierarchical levels to result in significant changes in community structure and large ecosystem impacts. These alterations may be characterized by prolonged recovery and/or hysteresis, or may even lead to persistent state changes. From Smith, M. D., 2011b: An ecological perspective on extreme climatic events: a synthetic definition and framework to guide future research. *J. Ecol.*, **99,** 656–663.

and Breshears 1998; Haddad et al. 2002; Mueller et al. 2005; Thibault and Brown 2008).

There are several advantages to this synthetic definition of an ECE. First, it emphasizes the requirements for extremity from both a driver and response perspectives (**Figure 3**). Second, it identifies a priori the ecological mechanisms (**Figure 4**) that can lead to an ECE. In doing so, there is a basis for distinguishing between those instances where a statistically extreme climate period does not result in an extreme ecosystem response (**Figure 3**, dashed black arrow) from those instances where it does (**Figure 3**, solid red arrow). It also provides a framework for elucidating the mechanisms (individual–population versus species reordering versus species migration) that may give rise to these alternative outcomes (**Figure 4**). Finally, the definition excludes from consideration those instances where an extreme response results from some aspect of climate (e.g., changes in climate means) other than climate extremes (**Figure 3**, dashed red arrow; see Smith et al. 2009 for examples). The latter is important because mechanisms leading to an extreme ecological response driven by a gradual and chronic change in a climatic mean may differ from those associated with climate extremes (Smith et al. 2009).

4.07.5 Application of the ECE Framework

The utility of the ECE definition and accompanying mechanistic framework above for understanding the ecosystem consequences of climate extremes can be demonstrated by considering two examples. The first is from an on-going experiment designed to examine the impacts of extreme precipitation regimes on the structure and function of the tallgrass prairie ecosystem (see Fay et al. 2000 for details). For over a decade, growing season precipitation regimes have been experimentally altered using rainfall manipulation shelters deployed over intact prairie, whereby periods of time between rainfall events have been increased by 50% without altering the total rainfall amount. The altered rainfall treatment has resulted in a three fold decrease in the mean number of growing season rainfall events, with the interval between events three times longer compared to the ambient regime. Such a regime is very different from what has been observed in the historical climate record, and thus, represents a statistical extreme (see **Figure 3** in Smith 2011b). However, the primary impact has been limited to reduced performance of only a few species (Fay et al. 2003), which has resulted on average in a 10% reduction in aboveground net productivity (Knapp et al. 2002; Fay et al. 2011). This modest alteration in ecosystem function has occurred without substantive changes in community structure, loss of species, or invasion by new species (**Figure 4**), and while the reduction in production is significant ecologically, it is well within the natural range in variability observed for this system (Knapp and Smith 2001). Thus, although a period of climatic extremity was imposed, the ecosystem appears to be relatively resistant to this type of climate extreme, and according to the definition above, the grassland has not experienced an ECE. This conclusion is based on both the lack of profound impact on the ecosystem as well as the absence of any mechanistic evidence that thresholds have been exceeded that could lead to an extreme ecological response (e.g., significant species reordering or loss of species, **Figure 4**).

A second example involves a regional climate extreme that occurred in 2002–03 across southwestern North America. This period was characterized by an extreme drought with respect to the long-term climate record and was accompanied by anomalously high temperatures. Here, the climate extreme resulted in widespread mortality of *Pinus edulis* (pinyon pine), a codominant species in pinyon-juniper woodland (Breshears et al. 2005). Such large-scale mortality events have been shown to shift ecosystem boundaries in the past (e.g., Allen and Breshears 1998) and rapidly alter ecosystem structure and function (e.g., Mueller et al. 2005), as well as significantly affect land surface conditions (Royer et al. 2011). Subsequent studies have linked pinyon pine mortality to drought-induced carbon starvation of individual trees (Adams et al. 2009). In this case, we can conclude that an ECE has occurred because the statistically defined climate extreme resulted in an extreme ecological response—one characterized by mortality of adult pinyon pine trees, which subsequently cascaded through the ecological hierarchy to have profound and potentially long-lasting impacts on the ecosystem.

The examples above can be viewed as the two alternative responses to climate extremes depicted in Figure 3. On the one hand, a statistical climate extreme was imposed, but did not result in an extreme ecological response for a tallgrass prairie ecosystem, and on the other hand, thresholds for extreme responses for pinyon-juniper woodland were clearly crossed (e.g., mortality of the dominant tree species occurred, Figure 4), resulting in large community and ecosystem impacts. A major challenge for the future will be to increase our understanding of how and why ecosystems may differ in their vulnerability to experiencing an ECE, whereby an extreme ecological response can be attributed to a climate extreme. Key to this will be placing greater emphasis on quantifying thresholds for ecological processes that when crossed may lead to extreme ecological responses, such as profound changes in ecosystem function and services. For example, in the case of the tallgrass prairie, independent studies of the responses of the dominant grasses, the dynamics of community structure, and the invasibility of the plant community all point to stability of the plant community as key to the resistance of tallgrass prairie ecosystem to the type of climate extreme imposed (Knapp et al. 2002; Nippert et al. 2009). Whether this will translate to ecosystem resistance to other types of climate extremity remains unknown and is the subject of additional research (see Figure 4 in Smith 2011b).

The value of the distinction between climate extremes and ECEs is also apparent when considering paleo-ecological records where extreme ecological responses, such as state changes or regime shifts, are a common feature; yet, these are not always attributable to climate extremes or even abrupt changes in climate (Williams et al. 2011). While there are recent examples of extreme ecological responses, such as the widespread mortality of tree species caused by extreme drought mentioned above (e.g., Allen and Breshears 1998; Breshears et al. 2005; Mueller et al. 2005; Bigler et al. 2006, 2007; Gitlin et al. 2006), the paleo-record also is replete with examples of extreme ecological responses, particularly during the late Quaternary. Williams et al. (2011) characterized these by their rapid shifts in species abundances and changes in community composition driven by large-scale mortality and species migration, resulting in persistent regime shifts or state changes. Thus, at this timescale, it is clear that extreme ecological responses as defined above can be relatively common and apparent features of ecological systems. However, as with climate extremes, a baseline for the range and magnitude of responses for ecological systems is essential for providing necessary context for determining when extreme ecological responses occur, as exemplified by the case studies from the late Quaternary and early Holocene (Williams et al. 2011).

Once climatic and ecological extremity are recognized, explicit attribution of a climate extreme as the driver of an extreme ecological response is the critical next step in determining whether an ECE has occurred (Smith 2011b). The severe drought of 2002–03 in the southwestern USA provides a clear example of an extreme ecological response that can be explicitly linked to a climate extreme. Research by Breshears et al. (2005), Adams et al. (2009), and Royer et al. (2011) demonstrates the unprecedented magnitude of mortality of the dominant tree species, *P. edulis*, as a consequence of a statistically extreme drought. Moreover, Royer et al. (2011) showed that the die-off of overstory vegetation had regional-scale effects on near-ground solar radiation, with the potential for cascading and long-term impacts for a broad range of ecological processes. Despite this and other examples of extreme ecological responses driven by periods of climatic extremity, such as severe droughts and rapid changes in temperatures (Weaver 1968; Bigler et al. 2007; Gitlin et al. 2006; Williams et al. 2011), Williams and colleagues show that demonstrating causality remains a significant challenge. This raises the questions of how often and under what circumstances do ECEs actually occur and how and why ecosystems may differ in their vulnerability to ECEs.

4.07.6 The Rarity of ECEs

While the studies described above have increased our understanding of the causes and consequences of ECEs, the rarity and a possible increase in the frequency and intensity of climate extremes in the future have prompted a number of researchers to experimentally impose climate extremes on a range of systems. For example, Arnone et al. (2011) experimentally imposed an extremely warm year on intact tallgrass prairie monoliths from Oklahoma, USA, and found an immediate and large (~30%) reduction in aboveground productivity, driven primarily by the dominant C_4 grass species in the system. However, the change in aboveground productivity was within the range of interannual variability observed for tallgrass prairie, was not persistent over time, and was not accompanied by changes in plant community structure or composition. Similarly, with statistically extreme drought events applied to constructed European grassland communities for five consecutive years, Jentsch et al. (2011) showed a lack of large effects for a broad array of ecosystem responses measured. For example, above and belowground productivity remained unchanged across all years of the study, possibly as a consequence of complementary responses among plant species, and without a concomitant change in plant community composition.

The lack of extreme ecological responses in these and a number of other recent experiments (Van Peer et al. 2001, 2004; Marchand et al. 2005, 2006a,b; Milbau et al. 2005; Bokhorst et al. 2008; Kreyling et al. 2008; De Boeck et al. 2010b) suggests that ECEs occur much less frequently than their potential drivers – the climate extremes themselves, and possibly much less frequently than suggested by observational studies and the recent paleo-record. This may be, in part, due to the fact that observational studies are often conducted only when a climate extreme evokes an obvious extreme response (e.g., widespread mortality of a species). Therefore, understanding based on observational studies may be biased toward equating climate extremes with ECEs. In addition, one might conclude from these experiments that the systems being studied are resistant to the type and/or timescale of climate extremes imposed. However, it is difficult to rule out alternatives, such as (1) that the length of these studies was insufficient to capture an extreme response for the system in question, (2) that the treatments were not extreme in terms of the historic and recent paleo-climate record or what the system and its component species had previously experienced, or (3) that unique or rare combinations of climate extremes (e.g., temperature and precipitation with severe drought, see above) may be required to evoke an extreme ecological response. Overall, these studies suggest that ECEs may be difficult to induce experimentally, and that a diversity of approaches, and a broad assessment of different types of climate extremes may be required to more fully determine the causes and consequences of ECEs.

4.07.7 Ecosystem Sensitivity to ECEs

It is clear from the section above that ECEs in which a climate extreme, such as a heat wave or drought, or combination of climate extremes results in an extreme ecological response occur much more rarely than the climatic drivers of these events. Moreover, it is likely that a single climate extreme will not generally result in an ECE unless it is of exceptional magnitude and duration. Instead, the trigger for eliciting an extreme ecological response is likely more complex, potentially involving multiple climate extremes, with the timing and sequence of these important events (De Boeck et al. 2009; De Boeck et al. 2010b). These, in turn, may interact with additional factors, such as insect outbreaks or other disturbances (Jentsch et al. 2007), as well as key attributes of the ecosystem (e.g., longevity of the dominant species, Smith et al. 2009). This complexity, as well as our inability to predict the occurrence and nature (severity, duration, etc.) of climate extremes, makes predictions as to which ecosystem will be more or less vulnerable to experiencing an ECE difficult, if not impossible. However, based on the framework presented in Figure 4, general predictions can be made about what factors may result in an ECE. For example, if a climate extreme causes widespread mortality of a dominant species, as in the case of the 2002–03 drought across southwestern North America, which caused widespread mortality of pinyon pine, then the expectation is that the ecosystem response will likely be extreme. One might expect that ecosystems dominated by species that have evolved under stressful conditions (e.g., species in arid environments) might be less susceptible to prolonged drought or heat waves, making those ecosystems more resistant to the occurrence of ECEs than those ecosystems dominated by less stress-tolerant species (e.g., species in mesic environments). Ultimately, our basic understanding of ecosystem resistance and resilience to these rare climatic periods will have to increase substantially if we are to make predictions about vulnerability.

4.07.8 Future Directions of Climate Extremes Research

It is important to consider how climate extremes and ECEs have been studied in the past, and the advantages and limitations of these approaches, to provide a context for what should be the research priorities in the future. To date, the majority of studies of climate extremes might best be described as opportunistic. These opportunistic studies arise (1) from concerted research efforts initiated after a period of climatic extremity is recognized (e.g., Allen and Breshears 1998), or (2) when a climate extreme occurs during the course of an ongoing observational or experimental study (e.g., Haddad et al. 2002; Breshears et al. 2005; van Ruijven and Berendse 2010). Although these opportunistic studies, particularly those involving observational approaches, have the ability to capture large spatial and temporal scales, they often lack replication and cannot control for characteristics of the climate extreme (type, timing, magnitude) or for other covarying factors (e.g., disturbance regimes, pest outbreaks). Such studies also are limited in their ability to assess interactions between different types of climate extremes (e.g., severe drought versus heat wave) or other factors, such as disturbance – and, of course, opportunistic studies are ultimately contingent upon a period of climatic extremity occurring during the lifetime of the study.

To overcome these limitations, there are a growing number of studies that experimentally impose climate extremes via field experiments (e.g., Marchand et al. 2005; Jentsch et al. 2007; Bokhorst et al. 2008; Smith 2011b). Indeed, many of the most recent papers identified in Figure 1(b) report on responses to experimentally imposed climate extremes. While these experiments offer the advantage of greater control over the nature of the climate extreme imposed when compared to opportunistic studies, they have to date been limited to a single climate extreme level (e.g., a 100-year drought or 30-year heat wave; but see Smith 2011b) imposed at a relatively small spatial scale. Moreover, few have considered interactions between different climate extremes (see White et al. 2000; van Peer et al. 2004; Jentsch et al. 2007; Smith 2011b) or other factors (e.g., disturbance, N deposition; e.g., Wang et al. 2008), and rarely have they addressed the role of multiple periods of climate extremity or the timing or sequence of climate extremes (De Boeck et al. 2009; Miao et al. 2009).

Opportunistic studies also are limited with respect to their ability to document the full extent of responses of ecosystems to climate extremes and their vulnerability to ECEs. However, opportunistic studies have been very successful in detailing ecosystem impacts of large magnitude as a consequence of crossing one or more thresholds for extreme responses (e.g., species reordering or species loss). Thus, they tend to capture the full magnitude of ECEs more often than experiments. This is because attention is typically not drawn to a climate extreme unless large ecosystem consequences are readily apparent (e.g., widespread mortality of a dominant species), and consequently those climate extremes that have limited impacts, or those that would not be considered ECEs by definition, tend to be understudied with the opportunistic approach. Experiments, on the other hand, have the potential to capture responses to multiple levels of climate extremes across the full range of hierarchical levels (Figure 4). Clearly, for experiments to have their greatest value, they need to be imposed at large enough scales and for long enough periods of time so that responses will not be constrained to the individual or population level (Smith et al. 2009). Otherwise, it will be difficult to determine if the lack of large impacts or the absence of evidence for exceeding extreme response thresholds is due to the limited duration, or scale of the experiment, or because the system is resistant to a particular climate extreme. Despite this limitation, experiments do have the ability, if designed properly, to identify those critical ecological thresholds that may result in an extreme response, whereas opportunistic studies do not.

Given the possible increase in frequency, severity of climate extremes (Solomon et al. 2007), and that even without such an increase climate extremes will still occur, it is clear that we should continue to opportunistically study these important drivers of ecological dynamics and change. Despite their limitations, opportunistic studies have significantly advanced our understanding of the vulnerability of ecosystems to ECEs. However, large-scale and long-term field experiments designed specifically to address critical gaps in our mechanistic understanding of how and why ecosystems may differ in their sensitivity to experiencing ECEs are more urgently needed. Some of the key features of future experiments that can address these research gaps are summarized here (see Smith 2011b):

1. For essentially all major ecosystems and biome types globally, we lack detailed knowledge of the magnitude, type, and combination of climate extremes that are most likely to result in response thresholds being exceeded and consequently for ECEs occurring. This is a daunting challenge, but at the very least, future experiments should impose periods of climate extremity at multiple levels using, for example, a replicated regression approach, whereby multiple levels of a climatic parameter can be applied in a statistically powerful way (Cottingham et al. 2005). With such an approach, climate extremes field experiments could follow the example of growth chamber and greenhouse studies that have successfully assessed response thresholds of individual species to temperature and water deficits (e.g., Hamerlynck et al. 2000; Larcher et al. 2010).
2. Also needed are experiments that impose multiple levels of climate extremity at different times of the year, or as multiple occurrences and/or in different sequences within and between years. These types of experiments can address issues of timing and the potential for antecedent (e.g., cumulative, compounded or sequential) effects of climate extremes (Paine et al. 1998; De Boeck et al. 2009).
3. Because climate extremes often occur in combination naturally, it is also critical that we continue to assess interactions between different types of climate extremes (e.g., severe drought and heat waves) at different levels of extremity. Other factors, such as changes in climate means, species diversity, trophic interactions, or disturbance regimes (see Jentsch et al. 2007), also should be considered as these may interact with climate extremes to result in the most extreme and persistent ecological responses (e.g., state changes and hysteresis, Paine et al. 1998; Smith et al. 2009).
4. Manipulations that may hasten or mimic the crossing of extreme response thresholds, such as removal of a dominant species from an ecosystem or experimentally invading systems to simulate the immigration of novel species, are needed to more mechanistically assess the vulnerability of ecosystems to experiencing an ECE.
5. Comparative studies of different ecosystems or biome types exposed to a range of climate extremes are also needed to elucidate the potential mechanisms underlying differential sensitivity, and whether these mechanisms are similar or different between ecosystems or biomes. Such comparative studies could include sites that differ in the longevity or diversity of species (Smith et al. 2009), or ecosystems that may be more or less vulnerable to climate extremes based on, for example, their sensitivity to changes in climate means.
6. Experiments need to measure ecological responses at multiple hierarchical levels (individual to ecosystem) and be conducted for sufficient periods of time, and at large enough scales to ensure that the entire range of ecological responses, and their respective thresholds are fully captured for the ecosystem in question.
7. Finally, advances in experimental infrastructure need to be made to allow researchers to impose realistic climatic extremes on organisms and entire ecosystems. Particularly challenging is imposing extremely high temperatures (more than 10 °C above ambient) under field conditions without potentially confounding artifacts (De Boeck et al. 2010a). For example, De Boeck and Nijs (2011) describe an alternative control method for infrared heaters, which are often employed to impose heat waves on terrestrial ecosystems, to avoid the potential confounding factors of plant responses to heating. Many more advances like these are needed if we are to increase our understanding of the role of climate extremes in ecological systems.

As previously mentioned, a key knowledge gap is our lack of understanding of the types and timescales of climate extremes that will lead to ECEs, as it is clear that statistically extreme climatic conditions often do not result in extreme ecological responses. Such resistance to climate extremes, and the mechanisms responsible, are as important to understand and identify as the attributes of ecosystems that make them vulnerable to experiencing an ECE. It is likely that the intensity, timing, and duration of periods of climatic extremity will interact in important and surprising ways (De Boeck et al. 2010b). However, we know very little about how ecological systems will respond to these potential interactions and whether or not they will result in extreme ecological responses. In addition, because the frequency of climate extremes could increase in the future, research is needed that addresses how repeated climate extremes may impact ecological systems and whether resistance or resilience develops over time, or if ECEs will become more frequent. Because increases in climate extremes could be accompanied by changes in climatic means, climatic variability or both, a key question is whether these aspects of climate change would increase or decrease the vulnerability of ecological systems to climate extremes. Research is also needed that addresses the role of multiple levels of diversity–genetic, species and trait, in determining the ecological and evolutionary consequences of climate extremes for organisms and their potential feedbacks on ecological processes (Schoener 2011). For example, Beierkuhnlein et al. (2011) showed how ecotypes of a key European grass species, each adapted to differing climate means, respond differently to climate extremes. However, the performance of these ecotypes could not be predicted from the climate in which they originated. This suggests that genetic and phenotypic diversity can play an important role in determining ecological responses to climate extremes, but that these effects are complex. Without doubt, much more research is needed here.

4.07.9 Conclusions

The study of climate extremes is a relatively new emphasis in ecology (Figure 1). This is despite the long-standing recognition of their importance by paleo-ecologists (Williams et al. 2011) and evolutionary biologists (Combes 2008). Although climate extremes have always been a feature of climate, their frequency of occurrence and intensity could change in the coming decades. Thus, an increasing recognition of their importance in driving contemporary ecological dynamics is needed. Ecologists need to bring a variety of approaches to expand our mechanistic understanding of how and why ecosystems may differ in their vulnerability to climate extremes. Furthermore, knowledge of the thresholds of ecological responses that may trigger dramatic ecological consequences needs to be incorporated into scenarios of future ecosystem dynamics at the global scale.

Acknowledgments

Much of this work represents a synthesis of ideas from talks presented at a 2010 Ecological Society of America Symposium and subsequent papers published in a special issue on Climate Extremes in 2011 by *The Journal of Ecology*. I am grateful for the contributions of the participants in both of those endeavors. I am also grateful for support from the U.S. Department of Energy, Office of Science (PER) (Grant No. DE-FG92-04ER63892), the USDA CSREES Ecosystem Studies Program, and the NSF Ecosystems and LTREB programs (Grant No. DBI-04214427).

Glossary

C_3 photosynthetic pathway The biochemical pathway used by most plants to fix carbon dioxide from the atmosphere. The pathway is associated with an enzyme, Ribulose Bisphosphate Carboxylase-Oxygenase (RUBISCO), which catalyzes the fixation of CO_2 and produces a C_3 compound in the early steps of the dark reactions of photosynthesis. This pathway experiences photorespiration because oxygen competes with CO_2 for RUBISCO.

C_4 photosynthetic pathway The biochemical pathway used by many tropical grasses, including corn, sugarcane, and sorghum, to fix carbon dioxide. The pathway is associated with an enzyme, phosphoenolpyruvate (PeP) carboxylase, which catalyzes the fixation of CO_2 and produces a C_4 compound in the early steps of the dark reactions of photosynthesis. This pathway does not experience photorespiration. C_4 plants maintain a lower stomatal conductance than C_3 plants and are better adapted to warmer, drier, and lower CO_2 conditions than C_3 plants.

Chronosequence A sequence of variables that change with time. Often, it pertains to studies of forests or soils across a landscape and similar climate that differ in their time since disturbance.

Leaf Area Index The projected area of leaves per unit area of ground.

Metabolism The set of chemical reactions in living organisms that maintain life.

Stomata The active pores on leaves that regulate the diffusion of CO_2, water vapor, and other trace gases into and out of leaves.

4.08.1 Introduction

Ecosystems provide a variety of services and functions that ameliorate the state of the air, land, and water, upon which life depends. A set of noteworthy ecological services that occur at local scales include regulating the supply and quality of water, soil formation, flood and erosion control, nitrogen fixation, pollination, food production, carbon sequestration, recycling of nutrients, and the provision of habitat (Costanza et al. 1997; Daily et al. 2000). At regional to continental scales, ecosystems play an integral part in determining the state of the atmosphere and climate system by regulating the exchange of energy and trace gases across the land–atmosphere interface (Arneth et al. 2010; Bonan 2008; Huntingford et al. 2011).

This chapter focuses on the exchange of energy between ecosystems and the atmosphere, as an ecosystem service. The overarching objective of this chapter is to evaluate the vulnerability of these services in the context of a changing world. To make this assessment, we first present information on the fundamental theory of energy and trace gas exchange and how they are regulated by an assortment of biophysical variables and feedbacks. We then examine the empirical and modeling literature to address such questions as: how could these services respond to climate trends and anomalies, disturbance, and land use change? Finally, we discuss how these services may be sustained under a changing climate and contribute to policy decisions by stakeholders.

4.08.2 First Principles

4.08.2.1 Why Is the Regulation of the Exchange of Energy and Trace Gases, an Important Ecological Service?

All living organisms extract energy and matter from their environment. They must do so to comply with a fundamental law of physics and biology—energy is needed to perform different forms of work (chemical, osmotic, mechanical) that enables individuals to acquire matter to grow, acquire additional resources, and out-compete their neighbors. And, they need energy to move, avoid predators, and ultimately

http://dx.doi.org/10.1016/B978-0-12-384703-4.00410-X

reproduce, thereby passing their genes to the next generation (Chapin et al. 2002; Odum 1997).

At the most fundamental level, mass and energy exchange between the land and the atmosphere is linked to photosynthesis by plants and cyanobacteria—solar energy absorbed by leaves and cyanobacteria is used to assimilate CO_2 and synthesize reduced carbohydrates $[(CH_2O)]_n$, the prime energy source for the majority of life on Earth. The subsequent extraction of chemical energy from carbohydrates is associated with a variety of heterotrophic or chemo-autotrophic metabolisms that use a hierarchy of biogeochemical redox reactions (Burgin et al. 2011; Falkowski et al. 2008; Schlesinger et al. 2011). One consequence of life's quest for energy is the loss of a suite of trace gases (CO_2, CH_4, C_5H_8, $C_{10}H_{16}$, H_2, H_2O, H_2S, N_2, NO, N_2O, NH_3, and O_2) as organisms extract energy from carbohydrates ($C_6H_{12}O_6$) or plant detritus by oxidation reactions.

This loss of matter from the ecosystem, in the form of trace gases, however, is a gain by the atmosphere. Consequently, trace gas transfer alters the atmosphere's chemical composition and modulates its 'greenhouse' warming effect (Ramanathan 1998); polyatomic gases, like CO_2, H_2O, CH_4, and N_2O, absorb and reradiate infrared radiation. The presence of 'greenhouse' gases in the atmosphere keeps the mean temperature of Earth above freezing, keeping water in a liquid state for its ubiquitous use by life. Over geological history, the exchanges of energy and biogenic trace gases have contributed to the coevolution of life and the atmosphere's chemical composition, and together have acted to stabilize the Earth's climate and made it hospitable for life (Lenton and van Oijen 2002; Walker 1984). In addition, the production of oxygen by photosynthesis is the ecological service that is responsible for the evolutionary explosion in complex, multicelled, Eukaryotic life, which depends upon aerobic respiration (Knoll 1992). In this context, it may not be an overstatement to say that mass and energy exchange between the biosphere and atmosphere is the ultimate ecological service.

4.08.2.2 What Are Key Environmental Processes and Variables Affecting Mass and Energy Exchange?

In quantifying energy and trace gas exchange of ecosystems, we must comply with limits established by the 'laws of physics.' First, there is a limited amount of solar energy available to a plot of land of a unit area—the solar constant is about $1365\,\mathrm{W\,m^{-2}}$ and roughly one-half of that energy is absorbed by the Earth's surface (Trenberth et al. 2009). Consequently, this limited amount of energy constrains the amount of moisture and nutrients that plants and other life forms can extract from within a plot of land. Second, the assembly of leaves on a plant and plants across landscapes is a complex process that exhibits scale-emergent properties. In the long run, this condition causes the metabolism of a landscape to be invariant with the size of the individual organisms—a landscape will either sustain a lot of small individuals with relatively low specific (mass-based) metabolic rates or a few large individuals with relatively high specific metabolic rates (Enquist et al. 1998).

The state and fate of the climate and ecosystems are intrinsically linked by a complex network of fast and slow, positive and negative feedbacks (Field et al. 1995; Kleidon 2009; Lenton and van Oijen 2002). On hour to daily time scales, the state of the weather drives plant and microbial physiology, like photosynthesis, transpiration, and respiration by autotrophs and heterotrophs. In turn, these processes feedback onto the state of the atmosphere through water, heat, and carbon dioxide exchange (**Figure 1**). On daily to seasonal scales, the integration of these physiological processes determines the net amount of matter that is assimilated by vegetation and how it is allocated to leaves, stems, and roots. The structure and function of the ensuing population of plants establishes a number of biophysical properties. Leaf area index, for instance, modulates mass and energy exchange by affecting how much sunlight is absorbed and by serving as a source and sink for trace gases. The shedding of senescent leaves and eventual death of plants, on yearly to decadal time scales, feeds biogeochemical cycles that sustain the carbon and nutrient pools and processes like mineralization, nitrification, ammonification, and denitrification, which feedback and determine the physiological capacity of the plants. Dynamic ecosystem processes, like disturbance, competition, reproduction, and dispersal, determine 'who is where' and 'how many are there.' These dynamical ecosystem processes operate on decade to century time scales and affect the biophysical attributes of the ecosystem that regulate energy exchange by modulating the biogeochemical fluxes into and out of the system and soil properties. In addition, there is a feedback with soil formation, which depends on weather, life, topography, parent material, and time (Jenny 1994). In sum, the feedbacks illustrated in **Figure 1** contribute to the fact that the global distribution of biomes and soils and the structural, functional, and biophysical properties they possess are closely interrelated with climate (Holdridge 1947; Jenny 1994; Stephenson 1990). The feedbacks among these linked processes also account for how different biomes have shifted, expanded, or contracted during different climatic states in Earth's history (Prentice et al. 1992; Woodward and Lomas 2004).

The most critical biophysical properties that regulate the fluxes of energy and trace gases include leaf area index, albedo, photosynthetic capacity, surface conductance, and aerodynamic conductance (Alton 2011; Dickinson 1983; Masson et al. 2003). In turn, the laws of physics constrain the morphology and function of leaves and root systems. Through natural selection, plants have developed leaves with a complex combination of shapes, sizes, and functions (Wright et al. 2004) that optimize the mass and energy exchange for the climate and habitat in which they exist (Taylor et al. 1975); biophysical interactions have forced leaves to evolve that are small to large in size, with broad- or needle-shapes, evergreen or deciduous habits, and C_3, C_4, or CAM photosynthetic pathways. Below ground, roots may be fibrous or tap-rooted and their vertical distribution may be concentrated in shallow soil layers or possess a subpopulation of pioneers that seek water deep into the soil or far beyond the horizontal reach of the plant canopy (Jackson et al. 1996). In essence, natural selection forced the rooting network of plants to vary in shape, with the ultimate outcome being volume filling and optimizing pursuit of water and nutrients within the soil column (Niklas and Enquist 2001).

Predicting how these biophysical properties may change is complicated by the fact that some of these properties are plastic and will seasonally vary, like photosynthetic capacity (Wilson et al. 2001; Xu and Baldocchi 2003). On longer time scales, the

temporal variation of a subset of biophysical properties may experience hysteresis; their properties will follow different temporal trajectories if the ecosystem is collapsing or recovering (Scheffer and Carpenter 2003; Suding et al. 2004); or the key biophysical properties may experience sudden switches if environmental stresses pushes an ecosystem into an alternative stable state (D'Odorico and Porporato 2004).

To assess how ecosystems regulate heat (temperature), water vapor, and carbon dioxide transfer into and out of the atmosphere, we start with the conservation of mass. It informs us that the time rate of change of energy, or trace gases, in the atmospheric reservoir is determined by the differences in fluxes entering or leaving the top and bottom of that reservoir. Metaphorically, one can envision the connection between the land–atmosphere fluxes and the atmospheric reservoir to how the level of water in a bath tub is determined, for example, by the balance, or imbalance, of the flows of water leaving the tap and entering the drain.

While the locus of energetic activity centers on the leaf and the cells of its mesophyll, the metabolism of the whole ecosystem is not as simple as adding up all of its parts and taking an average (Rastetter et al. 1992). To compute the metabolic activity of an ecosystem, one needs to integrate a set of nonlinear functions that experience non-Gaussian forcing by sunlight (Norman et al. 1981). One fraction of the leaves is sunlit. The amount of sunlight they receive depends on their angle relative to the sun (Ross 1976). But often, the sunlit leaves are exposed to light levels that saturate photosynthesis. The other fraction of leaves is shaded by those overhead. How much sunlight they receive depends on how deeply they are stacked in the canopy. These photosynthetic rates of the shaded leaves are highly sensitive to increases or decreases in sunlight. In principle, the arrangement of multiple leaf layers in a plant stand trap and scatter photons and modulates how much energy is absorbed or reflected (Dickinson 1983; Ross 1976). Ultimately, the amount of sunlight a vegetated canopy absorbs determines how warm the surface may get and how much water will be evaporated through transpiration (Jarvis and McNaughton 1986).

The radiative energy balance of a landscape is responsible for the thermal regime about organisms and ecosystems. Consideration of the net radiation balance is important because it provides the theoretical knobs that one may adjust to evaluate how energy exchange of ecosystems responds to changes in weather and climate, ecosystem structure, and plant physiology. The net radiation balance is defined as the algebraic sum of incoming solar shortwave radiation (R_{in}) minus outgoing, reflected, radiation (R_{out}) plus incoming terrestrial longwave radiation (L_{in}) minus terrestrial longwave energy that is radiated by the surface (L_{out}), which is in proportion to its absolute temperature to the fourth power. The net radiation (R_n) balance supplies the energy that drives sensible heat (H) and latent heat exchange (λE), conductive heat transfer in and out of the soil, and vegetation (G) and photosynthesis (P):

$$R_n = (1-\alpha)R_g + \varepsilon L_{\mathrm{in}} - \varepsilon\sigma T_s^4 = \lambda E + H + G + P \qquad (1)$$

The Penman–Monteith equation provides the guiding theory for examining how changes in surface properties of vegetation and ecosystems will alter latent heat exchange, the energy used to evaporate water (Monteith 1981). The Penman–Monteith equation is defined by the algebraic manipulation of the surface energy budget (eqn. 1), in conjunction with Ohm's law of resistance to model fluxes, and the linearization of several temperature-dependent functions like saturation vapor pressure and the emission of longwave energy—its derivation achieves the goal of replacing functions dependent on surface temperature with those dependent upon air temperature, a quantity that is readily measured at a weather station:

$$\lambda E = \frac{s(R_n - S) + \rho \cdot C_p \cdot G_H \cdot D}{s + \gamma + \gamma \dfrac{G_H}{G_s}} \qquad (2)$$

In eqn. 2, G_H is the boundary layer conductance for heat transfer ($\mathrm{m\,s^{-1}}$) and G_s is the surface conductance ($\mathrm{m\,s^{-1}}$); one can also pose this equation in terms of resistances, which are the reciprocals to conductance. Air density is denoted by ρ, specific heat of dry air is quantified by C_p, the psychrometric constant is γ, D is the vapor pressure deficit, and s is the slope of the saturation vapor pressure–temperature ($e_s(T)$) relation with respect to temperature. The slope of the saturation vapor pressure – temperature function, s, equals 145 $\mathrm{Pa\,{}^\circ C^{-1}}$ at 20 °C and it ranges between 32 and 473, as air temperature increases from -5 to 44 °C. Because $e_s(T)$ has a strong temperature dependence, a smaller fraction of available energy will be lost to latent heat exchange under cool climates than under warm climates. This effect reinforces dry desertlike conditions in the tundra and humid conditions in the tropics.

The aerodynamic conductance, G_H, is a function of surface roughness, friction velocity, and the thermal stratification of the atmosphere (Monteith and Unsworth 1990). Forests are aerodynamically rougher than short and smooth vegetation like crops and grasslands; the canopy conductance over a tall forest may be two to three times greater than that of adjacent grassland for a similar free-stream wind velocity. Hence, replacing tall vegetation with short vegetation reduces the fraction of available energy that is partitioned into latent heat exchange (Raupach 1995, 1998) and vice versa.

The surface conductance (G_s) connotes ecological and physiological information onto the Penman–Monteith equation (Jarvis 1976). In practice, this conductance is a function of leaf area index, soil moisture, plant functional type, and nutrient content of the leaves (Baldocchi and Meyers 1998; Kelliher et al. 1995; Schulze et al. 1994). A closed canopy comprised of well-watered fertilized C_3 plants will possess a higher conductance than a canopy with well-watered fertilized C_4 plants. Also, these plants will exert a higher conductance to vapor exchange than plant canopies that are open or experience stress due to soil moisture deficits or limited nutrients.

The leaf area index of native plant stands are either limited by water or light. Dense canopies with high leaf area indices ($\mathrm{LAI} > 3$) are able to form where rainfall is great and it exceeds evaporation. Conversely, sparse canopies form where rainfall is sparse or where potential evaporation far exceeds rainfall (Baldocchi and Meyers 1998; Grier and Running 1977; Sankaran et al. 2005).

The vapor pressure deficit that drives evaporation in the Penman–Monteith equation is not a passive variable. It depends on the depth of the planetary boundary layer and the fluxes of moisture into the bottom and top of that volume. The depth of planetary boundary layer, its rate of growth, and how much dry and moist air it may entrain from above are functions of the amount of sensible heat injected into the lower boundary layer (Jacobs and Debruin 1992; McNaughton and Spriggs 1986). In theory, the growth of the planetary boundary layer is a function of the virtual sensible heat flux and the gradient of potential temperature across the entrainment layer. When the growth of the planetary boundary layer intersects with the lifted condensation level, there is a chance for condensation and clouds to form, increasing the probability of precipitation (Siqueira et al. 2009) and reducing the amount of solar radiation at the Earth's surface.

4.08.3 Sensitivity to Environmental Stress

How well ecosystems may continue to serve the climate and the atmosphere depends on how they will respond to secular trends in a suite of environmental drivers that are associated with the emerging geological epoch, the Anthropocene (Steffen et al. 2007). Ongoing changes in the atmospheric environment—rising levels in carbon dioxide, temperature, nitrogen deposition, land management practices, atmospheric pollution, and variable changes in rainfall—are expected to impose both negative and positive effects on the metabolic activity of ecosystems that are direct and indirect (Field et al. 1995; Korner 2006). How well ecosystems respond to this suite of environmental changes depends upon their ability to tolerate, avoid, acclimate, and/or shift their domain—the alternative is death or extinction. Their response will also depend on antecedent conditions, if the changes are gradual or fast, and whether extreme events occur that cross certain thresholds (Porter and Semenov 2005).

While this chapter focuses on vulnerability of ecosystem energy, and trace gas, exchange to climate, we also cannot ignore human-induced land use change as it is an agent of the new Anthropocene epoch (Steffen et al. 2007). Land use change is occurring through deforestation, afforestation, fire, disease, successional ecosystem dynamics, and invasive species and is covarying with climate (Kabat et al. 2004). Because land use change affects the composition of the ecosystems and the biophysical properties they possess, land use change may have an immediate and stronger impact on the regulatory services that ecosystems provide through trace gas and energy exchange than climate change, *per se* (Bounoua et al. 2002; Diffenbaugh 2009; Kabat et al. 2004; Levis 2010; Pongratz et al. 2009; Snyder et al. 2002).

In the following three subsections we discuss general insights on how mass and energy responds to environmental change drawing on information from extensive and long-term field studies, feedback theory, and comprehensive modeling exercises.

4.08.3.1 Lessons from Field Observations

A community of micrometeorologists and ecologists are studying how sensitive mass and energy exchange may be to a variety of climate, weather, and ecological forcing through a global network of long-term flux studies (Baldocchi 2008; Baldocchi et al. 2001). Studies exceeding a decade in length are proving noteworthy in understanding how mass and energy exchange at individual sites may vary with year-to-year modulation in sunlight, temperature, and rainfall (Granier et al. 2008; Grunwald and Bernhofer 2007; Ilvesniemi et al. 2010; Pilegaard et al. 2011; Urbanski et al. 2007; Zha et al. 2010). These long-term studies are also adept at determining how mass and energy exchange of various ecosystems respond to stressful conditions like drought, heat-spells, and freezes (Granier et al. 2007; Gu et al. 2008; Reichstein et al. 2007b; Rotenberg and Yakir 2010; Teuling et al. 2010; Zha et al. 2010).

The European 2003 heat-spell and drought has proven to be an excellent test case on how ecosystem carbon and water exchange vary with warming and drying (Granier et al. 2007; Reichstein et al. 2007b; Teuling et al. 2010). Initially, more sensible heat was lost by the regional forests than grasslands, as forests were optically darker and exhibited greater stomatal control on gas exchange. As the drought prolonged, the grasslands with shallow root systems depleted their soil moisture reserve. This forced the grasslands to become warmer than the forests and accelerated the heat-spell across Europe. Hence, grasslands were more vulnerable to drought than surrounding forests. With respect to variation within forest types, beech and broadleaved Mediterranean forests were found to be more sensitive to the drought and heat-spell than spruce and pine forests (Granier et al. 2007).

Studies across ecological or climatic gradients reveal how mass and energy exchange responds to leaf area, rain, temperature, and sunlight (Reichstein et al. 2007a; van Dijk et al. 2005; Yi et al. 2010), CO_2 and N deposition (Magnani et al. 2007), or varied plant functional types (Anderson-Teixeira et al. 2011; Baldocchi et al. 2000, 2010). Long-term studies of contrasting pairs, or clusters, of sites allow investigators to study how a change in land surface properties affect mass and energy exchange of natural ecosystems. A condensed survey reveals published studies have compared mass and energy exchange of (1) savanna versus grasslands (Baldocchi et al. 2004; Scott 2010), (2) deciduous versus evergreen broadleaved forests (Baldocchi et al. 2010), (3) deciduous broadleaved forest versus evergreen conifer forests (Baldocchi et al. 2000; Eugster et al. 2000; Zhang et al. 2001), (4) boreal forests versus grasslands (Zha et al. 2010), and (5) conifer forests versus desert (Rotenberg and Yakir 2011). Another body of literature studies the effects of disturbances, like fire, logging, deforestation, and insect infestation, on mass and energy exchange using a network of sites distributed across a chronosequence (Amiro et al. 2006a; Anderson-Teixeira et al. 2011; Brown et al. 2010; Liu and Randerson 2008; Montes-Helu et al. 2009) or natural regeneration (Juang et al. 2007; Lohila et al. 2010; Stoy et al. 2006).

The replacement of semi-arid woodlands with grass and shrubs yields some counterintuitive findings on mass and energy exchange worth discussing. Woody vegetation is darker than surrounding shrub and grasslands, causing savannas and pine forests to absorb much more solar energy (Baldocchi et al. 2004; Montes-Helu et al. 2009; Rotenberg and Yakir 2011). But more effective convective heat loss and evaporative cooling cause aerodynamically rough forests to experience lower surface temperatures than contrasting smoother landscapes.

In order to synthesize the information contained in the cited papers, we extract information on annual sums of energy fluxes for broad climate zones and plant functional types of interest (Table 1); these data are from a global network of long-term carbon, water, and energy flux measurements, FLUXNET (Baldocchi et al. 2001). The amount of incident solar radiation (R_g) ranges between about 3.4 and 6 GJ m^{-2} y^{-1}. Lowest values of solar energy inputs are associated with northern ecosystems, like wetlands and boreal forests, and the greatest values associated with subtropical semi-arid ecosystems, like savanna. Intermediate levels of solar radiation are received by ecosystems in humid tropical regions because skies are often cloudy. Ecosystems with the most net radiation (R_n) do not correspond with regions receiving the most sunlight. Evergreen broadleaved forests are optically dark so they retain a relative high fraction of ample incident sunlight. Conversely, grasslands and wetlands in northerly temperate and boreal climates are reflective and retain the least.

Distinct plant functional types (forest, grasslands, shrublands) in different climates (tropical, temperate, boreal) use their available energy differently. Regarding the amount of net radiation used to drive latent heat exchange (λE) over the course of a year, the highest fraction, on average, is associated with grasslands (65%) and the least is associated with evergreen needle-leaved forests (42%). The lowest fraction of net radiation that is consumed by sensible heat (H) is associated with crops (23%) and the largest fraction is associated with savanna woodlands (44%). Solar energy and its partitioning into sensible and latent heat exchange are poorly correlated with net ecosystem carbon exchange (NEE) at annual time scales. This occurs because NEE represents the difference between offsetting fluxes from two different pools (vegetation and soil) that are controlled by different factors.

So far, we have discussed many of the direct effects of ecosystems on energy and trace gas exchange. There are many conditional and indirect effects that play pivotal roles in how mass and energy exchange respond to climate conditions and

The data were extracted from annual sums from the FLUXNET database, www.fluxdata.org

land use. Important conditional factors include the length of the growing season, presence and absence of snow, the extent of the dry and wet season, soil fertility, and time since disturbance.

Time since disturbance has a noteworthy impact on mass and energy exchange, as determined from chronosequence studies. In the boreal forest, for example, albedo and the fraction of net radiation that was consumed as latent heat decreased in a nonlinear function with time since disturbance (Amiro et al. 2006b). What does this information tell us about reforestation or deforestation? Until recently, it was conventional wisdom that forests evaporated more water than grasslands under similar conditions causing runoff and water yield to be greater from woodlands that were cut and replaced by grass. New information, from a 30-year record of a gauged watershed in Wales, has changed this perception. The investigators found that forest evaporation decreased with stand age to the extent that the forest now evaporates as much or less than a neighboring grassland (Marc and Robinson 2007).

Another indirect factor of interest is biodiversity. An initial inspection of the FLUXNET database found that an increase in the number of dominant deciduous tree species reduced the fraction of absorbed energy that is lost as latent heat (Baldocchi 2005). It was hypothesized that the hydraulic conductivity of a mixed forest stand is less than a less diverse forest. Yet, reinspection of this hypothesis with a longer and more extensive dataset finds no significant relation between annual evaporation and the number of dominant species across a spectrum of deciduous broadleaved forests (Figure 2). Theoretically, evaporation is modulated by the way plants of different traits assemble to affect the leaf area index and stomatal conductance of a landscape (Jarvis and McNaughton 1986), rather than number of species, *per se*.

4.08.3.2 Lessons from Feedback Theory

Many positive and negative feedbacks act upon energy and trace gas exchange and connect ecosystems and the atmosphere (Brubaker and Entekhabi 1996; Field et al. 1995; Jacobs and Debruin 1992; McNaughton and Jarvis 1991; van Heerwaarden et al. 2009). In the following, we will discuss feedbacks that control surface temperature and soil moisture because they establish the respective gradients against which heat and moisture are lost from an ecosystem and transferred to the atmosphere.

To quantify the positive and negative feedbacks that conspire to increase or decrease surface temperature, it is best to examine them through the lens of the surface energy balance and its coupling to the planetary boundary layer (Figure 3); in this figure, the term in each box is assumed to experience a positive increase; the sign and color of the arrow that follows defines whether the linked process increases (+, red) or decreases (−, blue) (Harte 2001).

An increase in surface temperature would initiate three parallel feedback loops. One loop would increase sensible heat exchange (H). A second loop increases the amount of longwave energy lost by the surface, causing a reduction in the net

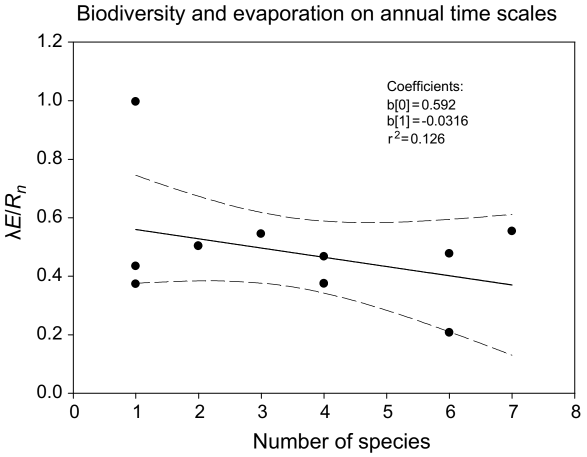

Figure 2 Correlation between number of dominant overstory tree species and annual evaporation. We evaluated evaporation in terms of latent heat exchange and normalized it by the net radiation budget of the plant stand. This analysis is based on data from the FLUXNET database at www.fluxdata.org. The slope is not different from zero at the 5% probability level ($P = 0.256$).

Figure 3 Feedback loops associated with surface temperature (T_s) through the interactions between the surface energy balance, the state of the atmosphere (humidity and temperature), growth of the planetary boundary layer, and the physiological status of the vegetation. Undefined terms include air density (ρ), vapor pressure (e_a), global radiation (R_g), albedo (α), incoming longwave energy (L_{in}), emissivity (ϵ), the Stefan–Boltzmann constant (σ), specific heat capacity (C_p), pressure (P), latent heat of evaporation (λ), soil heat flux (G), aerodynamic resistance (R_a), and potential virtual temperature (θ_v).

radiation balance (R_n). A third loop would increase the saturation vapor pressure of the surface (e_s). The first loop leads to an increase in the height of the planetary boundary layer (h), thereby entraining warm dry air from above the inversion of the planetary boundary layer. This sequence can promote evaporation by maintaining a strong gradient in humidity between the moist surface and the drier bulk atmosphere. The second loop decreases the amount of net radiation (R_n) that is available to drive sensible and latent heat exchange. The third loop increases the humidity gradient between the surface and free atmosphere that promotes evaporation (E) via latent heat exchange (λE). It also promotes an internal feedback loop by humidifying the boundary layer and decreasing stomatal resistance (R_s). These actions promote latent heat exchange, whose evaporative cooling retards surface temperature perturbations. Overall, the three feedback loops shown in Figure 3 interact to force a negative feedback on surface temperature. This leads to stabilization in surface temperature and helps explain why the mean growing-season surface temperature of plants from across the globe converge on a seasonally-weighted temperature near 21 °C (Helliker and Richter 2008).

The feedback loops illustrated in Figure 3 are fast feedbacks. This figure does not consider slower changes that would be associated with albedo and surface resistance as the functional type of vegetation and its leaf area change on slower ecological time scales (Chapin et al. 2008). Nor does Figure 3 consider the effects of snow or the presence or absence of reflective clouds, which may suppress or promote rainfall, change soil moisture, and alter leaf area index; removing forests, for example, will inhibit transpiration, which feeds the production of clouds and rain, which provide sufficient moisture to sustain forest vegetation (Anderson et al. 2011; Jackson et al. 2008).

To consider the slower feedbacks associated with soil moisture and canopy cover, we need to consider the interactions between evaporation, cloud generation, the solar radiation budget, rainfall, and leaf area index (Brubaker and Entekhabi 1996; D'Odorico and Porporato 2004; Koster et al. 2004). Figure 4 shows how moist soils promote evaporation, which humidifies the atmosphere and reinforces rainfall and soil moisture; ultimately, evaporation from moist ecosystems is limited by solar radiation (Budyko 1974; Donohue et al. 2007). Conversely, dry soils promote dry conditions and warm temperatures because the lack of evaporation inhibits evaporative cooling at the surface and a source of moisture for cloud formation and precipitation. The feedbacks associated with soil moisture are slower than those associated with surface temperature and can persist for weeks and months. The soil moisture feedbacks are most dominant at transitional 'Goldilock' regions that are neither too moist or dry, like the Great Plains of North America, the Sahel of Africa, and the Indian subcontinent (Koster et al. 2004; Seneviratne et al. 2006). There, they can set up alternative stable states of wet or dry conditions, initiated by spring climate anomalies (D'Odorico and Porporato 2004) or vegetation patterns (D'Odorico et al. 2007). On the other hand, the soil moisture-precipitation feedback may be stymied in situations where moisture advects across the landscape from nearby oceans, like the Gulf of Mexico or the Pacific Ocean.

On decadal time scales, we have to consider how these feedbacks modulate LAI and vegetation patterns (Baldocchi and Meyers 1998; Bounoua et al. 1999; D'Odorico et al. 2007; Donohue et al. 2007). On century to millennial time scales, another set of feedbacks come into play. They involve atmospheric circulation and help explain energy balance-land surface feedbacks for the Sahara desert (Charney et al. 1975) and Arctic

Figure 4 Feedback loop between precipitation (P), evaporation (E), solar radiation (R_g), LAI, and volumetric soil moisture (θ). These fluxes will interact to alter height of the boundary layer (h) and the humidity mixing ratio in the mixed layer (q_m). Other terms include air density (ρ), slope of the saturation vapor pressure–temperature function (s), the psychrometric constant (γ), humidity mixing ratio of the troposphere (q_T), and soil heat flux (G).

(Swann et al. 2010). An explanation for the persistence of the Sahara desert starts with the high albedo and warm surface temperature of this dry region with no vegetation. Together, these two facts reduce the net radiation balance of the surface despite its sunny locale. A regionally deficit radiation balance imposes a large-scale sinking action on the atmosphere, which reduces the relative humidity and inhibits convective action and precipitation. These links force a negative feedback on vegetation and albedo. In the Arctic, an expansion of the tree line would darken the albedo of the present tundra and could provide a new source of water vapor to the atmosphere through enhanced transpiration. This extra source of water would presumably expand over the ocean, warm it, melt the ice pack, and darken the ocean further. Together, these linked processes would further warm the land and reinforcing the feedback for more productivity by trees, lower albedo, and more transpiration.

4.08.3.3 Lessons from Comprehensive Land–Atmosphere Interaction Models

Biophysical models have the potential to tease apart the interactive effects of temperature and CO_2 and precipitation and land cover on current trends in climate. In practice, biophysical models can turn on or off processes that control energy exchange and compute how climate conditions may evolve (Bounoua et al. 1999; Brovkin et al. 2009; Claussen 1998; Dekker et al. 2010; Jacobs and Debruin 1992; Kleidon et al. 2000; Seneviratne et al. 2010; van Heerwaarden et al. 2010). For example, they can consider changes in a suite of biophysical variables (albedo, energy partitioning, and surface roughness) and biogeochemical and ecological processes (down regulation of photosynthesis and stomatal conductance, increased plant growth, and water use efficiency).

The simplest experiment is to consider a world with and without vegetation. Shukla and Mintz (1982) were among the first global modelers to demonstrate the role of evaporation from vegetation on the global fields of clouds, rainfall, temperature, and vertical motion using a coarse grid (four degree) model. Kleidon et al. (2000) performed a numerical experiment that considered a ‘green world’ versus a ‘desert world.’ They found that the presence of vegetation causes land evaporation to triple and this evaporative cooling reduces air temperature by 8 K, which reduces thermal radiation loss and increases the net radiation budget. Experiments like the green versus desert worlds set the upper limit on what to expect in how the climate may change with the state and extent of vegetation. In practice, land use change will exert its influence most greatly at regional and at smaller spatial scales, because 70% of the Earth’s surface is ocean. There is also the issue that atmospheric–ocean circulation changes, rather than a global average surface temperature, would have a greater impact on the state and extent of vegetation.

In the case of a ‘green world,’ the type of vegetation that is present or is replaced will have different effects on the climate system. In general, changing the type of vegetation indeed has smaller impacts on climate than removing vegetation altogether. Brovkin et al. (2009) recently assume the vegetation of the world to be either forests or grasses. They found that the climate warmed by 0.7 K if the vegetation was forested and it declined by 0.6 K if it was grass. In earlier work, Brovkin et al. (2004) reported that a biogeophysical mechanism that corresponded with changes in land cover caused global air temperature to decrease by 0.26 K. Conversely, biogeochemical processes forced the climate to warm by 0.18 K.

In another study, Bounoua et al. (2002) found land use change to have a greater impact on regional climate than on global climate. They reported that converting large swaths of forests and grasslands to crops cooled surface temperatures by 0.7 K during the summer and by 1.1 K during the winter. Conversely, converting tropical forests to C_4 grasslands warmed surface temperature by 0.8 K because C_4 grasses impose greater stomatal control on transpiration than C_3 grasses and trees. For a global average, they found temperate cooling was offset by tropical warming.

4.08.4 What Are Current Trends in Climate-Induced Changes in Mass and Energy Exchange?

Global warming is expected to accelerate the hydrological cycle and increase the rate of land evaporation. This expectation has led to a paradox in the observational record that is revealing a multidecadal trend in decreasing pan evaporation (Liu et al. 2004; Peterson et al. 1995; Roderick and Farquhar 2002). At present, three competing and/or complementary hypotheses are being debated to explain this phenomenon (van Heerwaarden et al. 2010). The first hypothesis revolves around the idea that the secular trend in decreasing pan evaporation reflects a moistening of the atmosphere by an increase in actual land evaporation (Brutsaert and Parlange 1998). The second hypothesis revolves around the consequence of global dimming (Stanhill and Cohen 2001) and its impact on the energy available to drive evaporation (Liu et al. 2004; Roderick and Farquhar 2002). This hypothesis is strongest in humid regions where evaporation in energy limited *a priori*, and is thereby sensitive to additional reductions in solar energy. The third hypothesis claims an association with a global stilling of the winds (Roderick et al. 2007). Most recently, van Heerwaarden et al. (2010) used a coupled energy balance/planetary boundary layer model to investigate this problem. They found that an increase in soil moisture leads to more actual evaporation and less pan evaporation under all conditions through feedbacks associated with evaporation and vapor pressure deficit and near surface temperature. On the other hand, increasing trends in continental-scale river runoff have been reported and they are attributed to a reduction in transpiration due to elevated CO_2 (Gedney et al. 2006).

The more difficult task is evaluating the low probability, high impact indirect responses to climate extremes that might cause major shifts in the landscape and its biophysical properties. These indirect effects operate on slow time scales, so their effect may not be obvious at first glance (Dekker et al. 2010). They have the potential to change an ecosystem from one stable state to another (Rietkerk et al. 2004). So they should not be ignored.

Removing keystone species or introducing an invasive species has the potential to disrupt the functioning of an ecosystem and change its composition, which in turn can affect biophysical forcings on the weather and climate. Prominent examples are insect outbreaks that defoliate wide swaths of forests (Brown et al. 2010), the defoliation of vegetation along the ‘bunny fence’ in Australia (Lyons et al. 1993), the exclusion or introduction of grazing (Allard et al. 2007; Bremer et al. 2001), and the occurrence or suppression of fire (Amiro et al. 2006b; Montes-Helu et al. 2009).

If future ecosystems experience warmer and drier conditions, an increase in fire frequency and severity may be in their future (Westerling et al. 2006). Looking at the energy balance across a chronosequence of burned sites, the general finding is that burnt sites are brighter than the forests they replace, reducing net radiation (Amiro et al. 2006b; Liu and Randerson 2008). With less available energy comes a reduction in sensible and latent heat exchange.

How vulnerable mass and energy exchange may be to climate-induced stresses may depend upon its successional stage—the late Eugene. Odum (1969) hypothesized that an ecosystem would be less vulnerable to environmental stresses as one proceeds along a successional sequence. Stoy and colleagues (2008) tested this hypothesis by measuring mass and energy fluxes over an abandoned field, an intermediate-aged pine forest, and an old hardwood forest. They found that the abandoned field was more susceptible to year-to-year variations in weather than the more established hardwood forest; the abandon field experienced the greatest year-to-year variation in evaporation; the pine stand fell in between. In a companion study, Juang et al. (2007) reported that differences in albedo caused the brighter grass field to be 0.9 K cooler than the pine forest and 0.7 K cooler than the hardwood forest. These radiative effects were smaller in magnitude and opposite in sign from the energy balance forcings associated with ecophysiology and aerodynamics. These factors cause the grass field to be +2 K warmer than the nearby forests. In support of the findings of Stoy et al., my group found that year-to-year differences in water (±86 mm) and carbon exchange ($\pm 113\,\mathrm{gC\,m^{-2}\,y^{-1}}$) of an annual grassland were much greater than the water (±61 mm) and carbon exchange ($\pm 46\,\mathrm{gC\,m^{-2}\,y^{-1}}$) of an adjacent oak savanna woodland with investment in deep roots (Ma et al. 2007; Ryu et al. 2008). Most recently, Zha et al. (2010) reported that annual evaporation was higher and more variable for a boreal aspen forest (405 ± 84 mm, mean ± standard deviation (s.d.)) and grassland (395 ± 90 mm), which are transitional ecosystems, than the black spruce (374 ± 34 mm) and jack pine (300 ± 20 mm) forests that approach climax states.

4.08.5 Policy/Stakeholder Recommendations

A number of lessons have been learned about mass and energy exchange of ecosystems and their vulnerability to climate that may have implications on policy and stakeholder decisions. First, there are no simple black–white answers. For example, we have learned that mass and energy exchange are associated with many positive and negative feedbacks that operate across a continuum of fast to slow time scales. This attribute buffers complex systems, like ecosystems, to many external perturbations, but it also makes them vulnerable to abrupt change if thresholds are exceeded. Also, complexity may make the response of ecosystems to environmental forcings susceptible to hysteresis—the functional response of the system depends on whether the forcing variable is increasing or decreasing.

Gertrude Stein is credited for stating ‘rose is a rose.’ We cannot take such poetic license and presume ‘a forest is a forest’ such that energy exchange from similar vegetation types is the same across regions, continents, or the globe. One evolving theme in the literature is how the mass and energy exchange of a forest system changes with time since disturbance, as does its vulnerability to climate perturbations. Together, this information must cause us to rethink how reforestation or deforestation may change the water balance of a region (Marc and Robinson 2007).

This said, the principles discussed in this paper give the ecological engineer 'knobs to turn' and information on how sensitive those knobs may be. In practice, many of the responses of mass and energy exchange to climate perturbations are conditional upon plant functional type, antecedent conditions, and climate statistics such as seasonal high and low extremes, rather than mean annual climate forcings. Tuning some 'knobs' of the energy balance will force immediate changes and other slow ones, like the position of biomes and the composition and properties of their vegetation if the climate where they occur changes (Jackson and Overpeck 2000). So, the pace of any change in long-term regional and local climate statistics would have a major impact on how well biomes shift, adjust, or adapt. In addition, the literature is clear on showing that weather can get locked into a behavior that may reinforce anomalous wet or dry conditions at regional scales, depending on antecedent condition. With positive feedbacks, the severity of these events can become quite intense like the 2003 European heat-spell, the 2010 Russian heat-spell, the Texas heat wave of 2011, and the floods that ravaged the Central United States during 2011.

Finally, ecosystems serve multiple purposes, which may have opposing effects. Hence, if we chose to engineer ecosystems for the benefit of the climate system, we have to be conscious of unintended consequences of our actions to manage and engineer landscapes to reduce ecosystem and climate vulnerability. For example, managing a landscape for sequestering carbon may lead to negative climate or air chemistry effects. For example, wetlands and forests are very effective carbon sinks. But the nature of flooding land will produce methane and nitrous oxides, which are powerful greenhouse gases.

4.09.1 The Climate Regulation Ecosystem Service

The Millennium Ecosystem Assessment (2003) proposed a classification framework for ecosystem services, which has four top-level classes: provisioning services, which are tangible goods and typically have well-defined markets; cultural services, based on aesthetic or amenity value, which also often have markets; regulating services, which stabilize the supply of either of the above, or in other cases reduce the risk of natural disasters; and supporting services, which are ecological processes without which none of the above would occur, but which are not themselves directly used by people. The latter two service classes seldom have existing markets.

The 'climate service' provided by ecosystems – in other words, their contribution to ensuring that the climate of a given area is within certain desired bounds – is usually classified as regulating service. A substantial part, but by no means all, of this service is related to the ability of ecosystems to take up carbon dioxide from the atmosphere. With the creation of tradable carbon credits – formally through the Kyoto Protocol, and whatever treaties may succeed it, and informally through a variety of 'voluntary' schemes – ecosystem carbon uptake and storage has effectively become a provisioning rather than a regulating service. Just like other provisioning services, it is a physical quantity with a market and a price. Land stewards can choose to manage their land to include carbon storage as one of the commodities it provides.

At the global scale, it is easy to demonstrate that terrestrial ecosystems provide a large and crucial climate service. Life exists on this planet because of the particular atmosphere that is present here. The composition of the atmosphere is dependent on the organisms and ecosystems that have coevolved with the atmosphere over a period of many billions of years. Without this biota, the temperature, rainfall, and atmospheric circumstances on Earth would be very different, and not able to support human life. Thus the 'total value' of the climate regulating services is infinite. The more useful (and difficult) question is what is the value of a marginal change in the climate service, for a subset of the planet of perhaps just a few hectares? Can this service be relied on in the future?

http://dx.doi.org/10.1016/B978-0-12-384703-4.00411-1

Specifically, is carbon storage biophysically dependable, against a backdrop of the substantial variability in the preindustrial climate of the Holocene, and the nonsteady state nature of the current perturbation of the global carbon cycle (National Research Council 2005)?

4.09.1.1 Mechanisms Delivering the Climate Service

The land surface modulates the climate in many different ways and at many scales. People have understood the microclimatic ameliorating effects of vegetation for centuries. It is the underlying principle of windbreaks, shade trees, and gardens. These effects are provided by slowing the wind, raising the humidity, intercepting solar radiation, and partitioning absorbed solar radiation into latent energy of evaporation rather than heat. The vegetated surface also helps to buffer humans from the consequences of climate extremes such as droughts, floods, or windstorms. These are all important parts of the 'climate service'. The focus of this chapter, however, is at a larger scale the role of the terrestrial surface in mitigating human-induced global change, specifically by acting as a sink for carbon dioxide, but also through non-CO_2 mechanisms (McAlpine et al. 2010). The climate system is never in a steady state, either interannually (e.g., Elis et al. 1978), or on longer timescales (Rial et al. 2004). The contemporary Earth climate system has, in addition, a significant human influence (National Research Council 2005). It is adjusting to a human-caused perturbation including the total emission of about $11\ \mathrm{Pg\,C\,year^{-1}}$ as carbon dioxide, $582\ \mathrm{Tg\,CH_4\,year^{-1}}$ as methane, $17.7\ \mathrm{Tg\,N\,year^{-1}}$ as nitrous oxide, and an average $19\,185\ \mathrm{Tg\,year^{-1}}$ of aerosols into the atmosphere (Solomon et al. 2007). These emissions are largely from the burning of fossil fuels, and with a significant additional component resulting from human-induced land cover change. Globally ecosystems absorb around half of the human-caused CO_2 perturbation, more or less evenly between the ocean and land (Prentice et al. 2001; Houghton 2003). The land uptake constitutes what is known as the 'terrestrial carbon sink'. It varies substantially in magnitude from year to year, much more so than the oceanic sink (Canadell et al. 2007; Rowhani et al. 2011). Inversion studies and *in situ* observations confirm that the terrestrial sink is widely distributed over the Earth's surface, though not evenly so (Gurney et al. 2004; Phillips et al. 1998). In addition, the pervasive human-induced changes in the land surface directly modify the climate through altering the surface fluxes of heat and water vapor.

This chapter focuses on the carbon storage aspect of climate on land. There is no general agreement on the relative contribution of the several processes thought to underlie the terrestrial carbon sink (Scholes et al. 1999). It is observed that when plants are exposed to higher levels of CO_2, their rate of carbon assimilation increases – a phenomenon known as CO_2 fertilization (Lobell and Field 2008). Many parts of the world are simultaneously experiencing N fertilization, either deliberately or as an unintended consequence of air pollution, which also increases production (Reay et al. 2008). Thirdly, large parts of Europe and North America are undergoing forest regrowth following clearing in past centuries – thus in the present time they act as carbon sinks (Nabuurs et al. 2003; Goward et al. 2008). A transient sink inevitably arises when a series of slow-turnover pools must be filled before respiration fluxes catch up with photosynthetic fluxes, trees must grow, die, and then decompose.

In addition to CO_2, several other radioactively active gases and particles produced or absorbed by the land surface also participate in the present imbalance in the global energy budget. The main ones are methane and nitrous dioxide, but carbon monoxide, a range of nonmethane hydrocarbons, and oxides of nitrogen contribute indirectly as precursors to tropospheric ozone, which is a powerful, but short-lived greenhouse gas. Organic aerosols and soot particles affect the radiation balance directly or indirectly by acting as cloud condensation nuclei. Change in the properties of the surface itself, especially its reflectance (known as albedo), alters the energy absorbed by the surface. For instance, when a bright surface such as snow is replaced by a dark surface such as a conifer canopy, the net result is warming (Betts 2000). There are other circumstances, such as the conversion of southwest Australian bushlands to agriculture, which could produce a cooling effect (Nair et al. 2007). 'Carbon', which has come to be used as shorthand for 'carbon dioxide', has tended to overshadow these other gases and processes, but this is a misleading simplification. Although CO_2 has the largest single direct human radiative forcing effect globally, in particular circumstances the other mechanisms are significant, even to the extent of overwhelming the carbon effect locally (e.g., Avila et al. 2012). If a net benefit to the climate system is the objective, rather than simply selling carbon into an undiscerning market, all the main known effects must be checked to ensure that the important ones have been taken into account under any given circumstance. It is perfectly feasible for an ecosystem to show an increase in carbon, but have a net detrimental effect on climate suitability for human purposes.

4.09.1.2 Pools and Fluxes

Carbon held within the ecosystem as a stock (also known as a 'pool', and having the general units of $\mathrm{g\,m^{-2}}$) has little direct effect on the climate as long as the total magnitude of that stock does not change. What causes a change in the global atmospheric concentration, and thus the climate, is a net flux of CO_2 out of the atmosphere and into the terrestrial ecosystem stock, or vice versa. Fluxes have units of $\mathrm{g\,m^{-2}\,year^{-1}}$; in other words they are rates. The confusion arises because fluxes are often measured as the difference between stocks at two times. It must always be remembered that it is not the magnitude of the stock that matters per se, but the change in the magnitude of the stock. When terrestrial stored carbon is sold, it is not the stock that is sold, but the flux it represents.

Carbon is held in terrestrial ecosystems in several interconnected pools of different sizes and turnover times (**Figure 1**). Turnover of some pools, such as the simple organic compounds and microbial biomass that make up the 'fast' pool, are fleeting – they may last only minutes to hours. Others, like live or dead leaves, decay over a period of months to years. Yet others, such as the trunks and coarse roots of trees, and the clay-associated organic carbon in the soil, last for decades. Finally, there are several pools that may persist for centuries or millennia such as charcoal, or the structurally complex, high

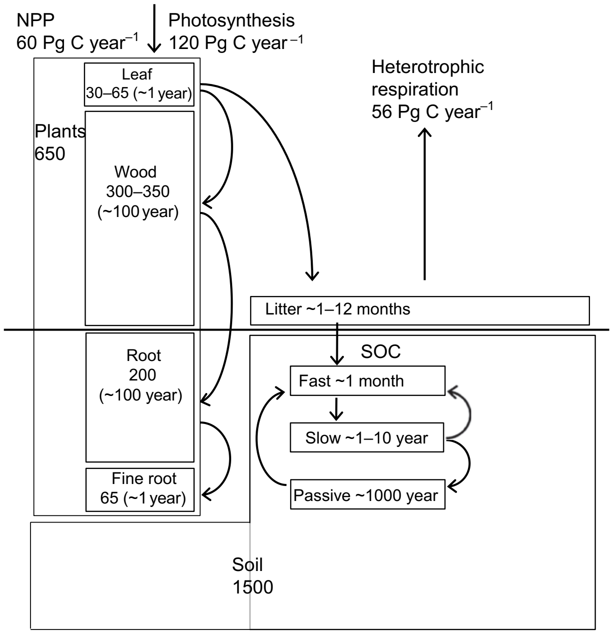

Figure 1 The key carbon stocks (boxes, Pg C) and fluxes (arrows, Pg C year^{-1}) in terrestrial ecosystems with their approximate magnitude at a global scale and the typical turnover times. The soil carbon excludes wetland soil and permafrost stocks.

molecular weight forms of soil organic carbon 'humic compounds'. The faster turnover pools are usually not counted when the carbon credits are calculated. There is an unwritten guideline that a pool must persist for 20 or more years before it is considered 'sequestered' rather than 'stored'. This aims to address the issue of the 'permanence' of land-stored carbon.

The total flux of carbon into and out of terrestrial ecosystems is always bigger than the portion of the flux that becomes stored, in most cases, one to two orders of magnitude bigger. For instance, at the global scale, over 100 Pg C year^{-1} is assimilated by the terrestrial vegetated surface through photosynthesis (Solomon et al. 2007). This overall amount is the gross primary production of the terrestrial biosphere. About half of this is directly returned through respiration by the plants themselves, leaving a net primary production of about 60 Pg C year^{-1}. In a steady state, which we would expect to be approximated in long-term undisturbed vegetation, virtually all of this would be lost back to the atmosphere through heterotrophic respiration (e.g., by microbes and animals feeding on the plants or their residues). Alternately, the carbon could be returned to the atmosphere relatively abruptly through a fire (for instance see Tilman et al. 2000) or major disturbance. In production landscapes, a significant amount of carbon is extracted through the harvest of crops or timber. A small amount of carbon is transported laterally out of the ecosystem in the form of aerosols, sediments, or dissolved organic carbon. Since the terrestrial biosphere is currently not in a steady state, about 2% of the assimilated flux is retained in terrestrial ecosystems, where it manifests as an increase in biomass, litter, and soil carbon (Malhi 2002; Solomon et al. 2007).

The small size of the stored flux relative to the turnover flux makes the accurate measurement of the former very challenging – the uncertainty in flux measurement is often larger than the stored flux. Similarly, the change in ecosystem stock is usually small, relative to the total stock, unless it is allowed to accumulate for several years. The relative error of estimation for the different components making up the global carbon stocks and fluxes range from about 1 to 90% (Scholes et al. 2009), with an average of 10–20%.

4.09.1.3 The Market for Climate Services

Despite the down turn and economic volatility in capital markets since the 2008–09 financial crisis, and a decline in carbon prices in 2011, the global carbon market amounted to USD 176 × 10^9 (Kossoy et al. 2012) in trades in 2011, making it one of the largest global commodity markets. Only a small part of this is 'land-based carbon'; the majority consists of reductions in industrial carbon dioxide or other greenhouse gas emissions. The main distinction is between the 'official market', e.g., that associated with international treaties such as the Kyoto Protocol, and the 'voluntary market'. The official market is always certified, in other words, backed up by accounting standards and audits. The voluntary markets are usually also certified, but with varying degrees of rigor. Since the signatories to international treaties are sovereign countries rather than individuals or corporations, countries are ultimately in control of the official market, and define its size through the regulations they set. The price of carbon in the official market is much higher than the price in the voluntary market, but so is the cost of participating in it.

Both the sellers and buyers of certified carbon credits are typically in the private sector. In the case of land-stored carbon, the sellers are land owners or land stewards, who through their management practices have caused the carbon density of the land (e.g., the mass of carbon within eligible classes per unit land area) to increase. In principle, the simultaneous effects of changes in the other greenhouse gases or land surface properties that also result from the management action must be considered as well, but in practice seldom are. The ultimate buyers are entities that have emission reduction commitments, which they either cannot meet or cannot do so at a price less than the market price for certified carbon credits. Between the sellers and buyers are a range of brokers and certifiers, and the agencies appointed by governments to oversee carbon trades. The complex structures and onerous certification rules add greatly to the transaction costs. Since the transaction costs do not scale proportionately with the amount of carbon involved, effectively, only large entities can trade profitably in carbon (Wise et al. 2009).

In the official market, two conditions need to be met. First, the carbon stored must be 'additional', in other words, as a result of some deliberate action, which otherwise would not have occurred. This is important, given that the terrestrial biosphere is taking up 2 Pg C year^{-1} without any intentional human assistance. In practice, since the mechanisms of the terrestrial carbon sink are not well understood, it is very hard (perhaps impossible) to attribute changes in land carbon between those arising from management and those that would have occurred anyway. Generally, a more or less arbitrary 'baseline' is agreed, and deviations from this baseline become the tradable commodity.

The second consideration is 'leakage' (Murray et al. 2004), which means that carbon storage in one location should not simply result in a carbon loss elsewhere. For instance, if a forest is permitted to accumulate carbon by restricting harvests, from where is the unchanged demand for wood being met? Again, this consideration is hard to implement with complete confidence. The usual approach is to insist on 'wall-to-wall' accounting within units large enough to encompass likely leakage, such as entire countries. If leakage is detected, it is hard to attribute it to any specific project.

The participation of 'non-Annex 1' countries (e.g., countries without emission reduction commitments, which translates mainly to developing countries) in the Kyoto Protocol carbon market is via the Clean Development Mechanism (CDM). It only recognizes a limited set of land-based storage activities (essentially, afforestation). The number of land-based carbon projects in the CDM has been low. Over and above the additionality and leakage conditions, CDM trades must demonstrate that they are consistent with sustainable development. For instance, a land carbon storage project, which results for instance in a large loss of biodiversity, water yield, or livelihoods, would in principle be disqualified.

Reduced Emissions from Deforestation and Degradation (REDD) introduces a new concept to the carbon trade. Instead of paying for the (imperfect) restoration of carbon on deforested land, it aims to pay a maintenance fee to keep the carbon on the land in the first place, while incidentally protecting biodiversity, water yield, etc. (Strassburg et al. 2009; McAlpine et al. 2010). This is a particular case of a general concept known as Payment for Environmental Services (PES). The principle difficulties with REDD involve monitoring what is cost effective, but nevertheless has sufficient sensitivity to detect partial loses (degradation); avoidance of leakage; ensuring that the land custodians are the major beneficiaries of the payment; and determining a reasonable price, given that the payments occur year after year, potentially forever – more like rental of stored carbon than a purchase of a change in stock.

4.09.2 What Controls the Magnitude of the Service?

In general, the carbon storage-related climate service offered by ecosystems is finite, since it represents an adjustment to a new equilibrium between carbon uptake and carbon loss. Once the equilibrium is reached, the net flux is zero and the stock quantity is unchanging in the long-term, even though large turnover might be taking place. Exceptions to this 'limited time' feature occur in the cases where carbon is continuously exported in a sequestered form (such as timber), or the captured carbon is used as a substitute for fossil fuels (e.g., biofuels), or in the 'rental' agreement in REDD. The service in general can be thought of as having a rate and a duration whose product constitutes the magnitude. Net primary productivity (NPP), ambient temperature, and soil waterlogging are the key determinants of the rate. The upper limits of soil carbon storage and biomass set the total magnitude.

4.09.2.1 Productive Potential

Terrestrial ecosystems cannot accumulate carbon at a rate exceeding net primary production. In practice, they generally store carbon at a much lower rate; nevertheless NPP is a good first order indicator of locations with high storage potential versus low storage potential. The broad-scale predictors of terrestrial NPP are well known: The absence of water stress, warm but not excessively hot temperatures, sufficient solar radiation, and a sufficient supply of the essential elements needed for plant growth (Running et al. 2004). The constraints applied by the carbon market – high transaction costs and the necessity for relatively frequent periodic inventories, means that ecosystems with low NPP, even if they technically could store a lot of carbon thanks to their large area – are not financially viable as storage locations. The carbon increment per area over a 5-year period is too low to detect except with an inordinate investment of effort.

Different broad ecophysiological groups of plants – plant functional types or PFTs (Grime 1977; Box 1996) – have different characteristic carbon uptake rates and sensitivities to environmental drivers. Some of the key top-level PFTs are plants with 'conventional photosynthesis', the C_3 pathway (most trees, herbs, temperate and wetland grasses, crops such as wheat and rice); C_4 photosynthetic systems (tropical grasses and crops derived from them, such as sugarcane and maize); and Crassulacean Acid Metabolism (CAM) succulents. The distribution of PFTs shows geographical patterns related to the climate, and specifically to water stress, and temperature.

Plants with CAM (including Agave, Cactus, and *Portulacaria afra*) are able to maintain productivity under conditions of severe water stress by temporally decoupling the carbon assimilation processes from the transpiration process. This may allow them to accumulate carbon at unusually high rates even in arid areas, but it does not relieve them totally from water constraints (Osmond 1978). The measured water use efficiency is about twice that of C_3 plants, but only a little better than that achieved by C_4 plants (Winter et al. 2005).

4.09.2.2 Mean Temperature

Other factors being equal, cool locations accumulate more soil organic matter and biomass than hot locations (Jenny 1980). This is apparent on altitudinal gradients – Montane forests have a higher carbon density than lowland forests, for instance, and on latitudinal gradients within, for instance, the Great Plains of North America (Parton et al. 1987). The reason is the strong and exponentially increasing effect that high temperatures have on increasing respiration rates, whereas carbon assimilation rates initially increase with temperature, but peak and decline above around 30 °C.

4.09.2.3 Waterlogging of the Soil

Soils which are waterlogged for more than a few weeks become anaerobic. Decomposition continues, but at a much reduced rate and via a methanogenic pathway rather than one that produces CO_2. These soils accumulate large amounts of carbon in the form of peat, both in temperate-cool areas and in nutrient-poor regions of the tropics (Hooijer et al. 2010). Paradoxically, flooding a soil for this purpose is counterproductive, because the methane and nitrous oxide generated offset the carbon gain (Sampson and Scholes 2000). Conversely, draining a peat box releases carbon dioxide, but eliminates a source of methane, and the two effects more or less cancel each other out.

4.09.2.4 What Determines How Much Carbon a Soil Can Store?

The global amount of carbon stored in soils vastly exceeds that stored in plant biomass or the atmosphere (1500–2000 Pg C for soils, 466–654 Pg C for biomass, 750 Pg C in the atmosphere; Prentice et al. 2001). Aside from the special case of waterlogged soils, described above, the maximum amount of carbon a given soil can store is mainly controlled by its texture (the fraction of clay and silt it contains) (Jenny 1980; Parton et al. 1993; Schimel et al. 1994) and the mineralogy of the clays (Six et al. 2002; Denef et al. 2004). The key slow turnover carbon pool in the soil is intimately associated with clays, and especially with large surface area clays such as smectites and illites (Six et al. 2002) (**Figure 2(a)**). Clayey soils facilitate the formation of C pools with slow turnover times due to the physical protection of SOM by clay minerals (Christensen 1992; Silver et al. 2000).

Once this storage surface is occupied, carbon can further accumulate as particulate organic carbon (tiny fragments of biomass), but is susceptible to relatively rapid loss (Six et al. 2002). Shallow or very stony soils can also not accumulate large amounts of carbon. Soil organic carbon stocks vary across ecosystems (**Figure 2(b)**) due to complex interactions among biotic and abiotic factors (Six et al. 2002; Schmidt et al. 2011).

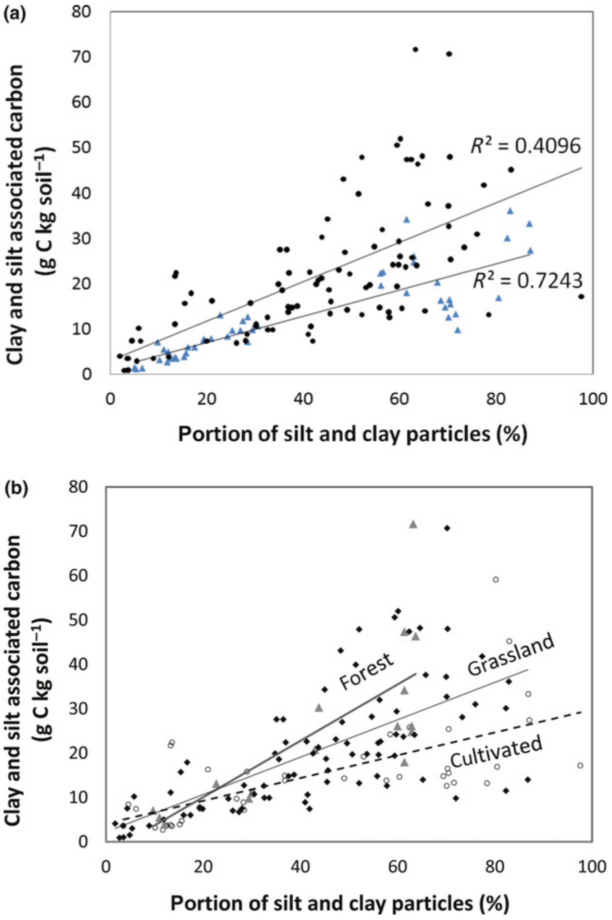

Figure 2 Silt plus clay content ('fines', as %) and silt and clay associated carbon concentration (g C kg soil^{-1}) for mineral particles 0–20 μm. (a) The effect of clay mineralogy (1:1 clays, e.g., kaolinite and serpentine, blue triangles; 2:1 clays, e.g., smectite and illite, black circles). (b) In relation to the type of ecosystem. Redrawn from data appendices in Six, J., R. T. Conant, E. A. Paul, and K. Paustian, 2002: Stabilization mechanisms of soil organic matter: implications for C-saturation of soils. *Plant Soil*, **241,** 155–176.

4.09.2.5 What Determines the Maximum Biomass on a Site?

The aboveground biomass that can accumulate on a site is determined by the vegetation cover and its height. Cover increases with rainfall, up to a maximum of essentially continuous canopy (Sankaran et al. 2005). Further biomass increases beyond this point rely on increasing height. The fundamental limits to the height that trees can reach are set by biomechanical considerations, such as the ability to anchor the tree against winds and the ability to lift water to the leaves (Koch et al. 2004). The importance of height, and the woody structural tissues needed to attain it, is why forests are the carbon storage ecosystems of choice. Ecosystems can store a substantial amount of carbon belowground, in the form of fine and coarse roots (Jackson et al. 1997), but belowground carbon does not count in many carbon market schemes, for no logical reason except that it is hard to see and tedious to measure.

4.09.2.6 Effects of the Disturbance Regime

Many terrestrial carbon storage projects involve the exclusion or reduction in frequency or intensity of disturbances that would otherwise lead to carbon loss. For instance, fire exclusion in savannas and grasslands, reduced-impact logging in forests, or reduced tillage in crop agriculture. The main disturbances, which disrupt the carbon cycle and can cause the loss of accumulated carbon, are fires, insect herbivore outbreaks, windstorms, harvest of plant material by humans, and disruption of the soil by cultivation or drainage. These disturbances are neither mutually exclusive, nor independent of one another. For instance, the dead material caused by a pest outbreak can increase the risk of fire.

Disturbance is often characterized as if it were a simple binary variable. Does it occur or not? In reality, disturbance regimes consist not only of the probability (or, equivalently, the frequency) of occurrence, but also the intensity of the disturbance and often more subtle characteristics, such as their relation to phenological or growth stages and their coincidence with other disturbances. A change to any of the determinants of a disturbance regime is likely to have consequences for the carbon cycle (e.g., in tropical savannas; Bird et al. 2000; Aranibar et al. 2003), but not all effects will be dramatic. Small changes in the regime will generally result in small changes to the stored carbon.

It is possible for an ecosystem to accumulate carbon in the presence of disturbances, provided that the carbon lost as a result of the disturbance is less than the carbon accumulated between disturbances. For instance, it is possible for a 'production forest', in which trees are felled rotationally to nevertheless have a higher average carbon density than a non-forested site (although probably less than an unharvested forest, **Figure 3**). Exactly how much more depends on the specifics of the management regime – how often does harvest

Pre-land use carbon density
Time (months or years)

Figure 3 A schematic representation of an ecosystem accumulating carbon following a change in land management. The top panel shows a simple case, where the carbon density rises according to a more or less logistic curve to a new equilibrium level. This can be approximated with linear segments defining a rate and duration of carbon storage. The lower panel shows a case, such as a rotationally harvested plantation, where there are repeated logistic segments interrupted by harvest or disturbance events. The long-term mean carbon density is nevertheless higher than in the preland use change case.

occur, what fraction of carbon is removed, and how much collateral damage is caused.

It is important to tolerate some level of disturbance in terrestrial ecosystems under management for carbon storage for several reasons. Firstly, an evolutionarily appropriate disturbance regime is required to maintain ecosystem characteristics such as biodiversity. Secondly, small disturbances help to preempt large disturbances (this point is discussed in more detail in Section 4.09.5). Thirdly, there is a theoretical argument (largely untested empirically) that protection from disturbances leads to the gradual loss of system capacity to cope with disturbance when it inevitably occurs – in other words, a loss of resilience (Gunderson and Holling 2002).

4.09.3 Thresholds and Tipping Points

4.09.3.1 Feedbacks in the Terrestrial Carbon Cycle

Feedback occurs when a change in one element of a system generates a response, propagated through the rest of the system, that eventually returns to have an effect on the first element that changed. Feedback is 'negative' (or stabilizing) when its net effect is to dampen the initial change and 'positive' when the net effect is to amplify it. Where more than one feedback pathway exists and the signs are different, the net effect can still be calculated, but this requires knowledge of the relative magnitudes of the individual effect terms and their nonlinear interactions. Positive feedbacks can lead to 'runaway change' if they are sufficiently large, but do not necessarily do so. In general, the effect of a positive feedback is simply to increase the size of the initial perturbation somewhat. If the net feedback effect is larger than the initial perturbation, the system is said have crossed a threshold, a 'tipping point' in popular terms, and will move under its own internal dynamics into a new stability domain. As a result of such interactions, new states can develop (Peters et al. 2004). There is an obvious positive feedback loop of terrestrial carbon with the rest of the climate system. An increase of temperature leads to the release of carbon from soils, which could lead to a further increase in temperature from the added radiative heating. But within plausible ranges of near future warming, the feedback by this mechanism alone is not believed to be strong enough to cause 'runaway warming' (Prentice et al. 2001). In conjunction with speculated (but not demonstrated) effects such as a large increase in vegetation fires, or a large accompanying release of methane from frozen soils, a runaway scenario leading to a persistently much warmer future state of the Earth's climate system may be possible.

4.09.3.2 Tipping Points

Moderately complex systems exposed to external forcing do not change smoothly and gradually, especially where some or all of the effect links between elements are themselves nonlinear, or lagged in time (e.g., Scheffer and Carpenter 2003, Rial et al. 2004). Rather, they appear to resist change or be insensitive to applied driving forces over some domain, and then change more or less abruptly. The climate system, including its biospheric and human system couplings, has all these characteristics. Therefore, the response of the terrestrial carbon cycle to increased effects from atmospheric and other climatic effects is unlikely to be continuous and incremental at the global spatial scale.

The terms 'tipping point' and 'threshold' have been used in a variety of ways in this context, not always consistently (Raupach and Canadell 2008; Lenton et al. 2008). The notions also become confounded with other limit-based ideas, such as (1) the amount of change that is policy relevant, (2) ethically important, (3) important for human welfare, and (4) ecologically important (Lenton et al. 2008; Kriegler et al. 2009; Martin et al. 2009). Often 'threshold' is used to describe either a more or less arbitrary level, which people agree not to transgress. Alternately, it may describe a point where the rate of change begins to steepen, but does not yet constitute a separation between two system states. The terrestrial carbon system has many such thresholds, which are important, but not necessarily critical.

In this chapter we use 'tipping point' exclusively to refer to a threshold where the internal dynamics of the system cause it to continue to change after the forcing effect has ceased, carrying the system quasi-irreversibly into a new state. Beyond the tipping point, the future state and development of the system is qualitatively different (Lenton et al. 2008). We consider it only 'quasi-irreversible', because although in the short term the system will not revert of its own accord, it may be possible to manage it back to the former state with some input of effort. In the longer term, another series of changes may be triggered, which eventually lead the system back to its original state.

Inherent in the notion of tipping points is the idea that a small perturbation in their vicinity can have potentially disproportionate, persistent impacts on the system. Such tipping points have been suggested to exist for several subsystems or spatial regions of the global terrestrial carbon system, within the plausible range of contemporary environmental change.

For instance, the melting point of ice near 0 °C constitutes a physically determined threshold with important consequences for the carbon cycle of frozen soils. If large areas of permafrost melt, their contribution to global atmospheric CO_2 and methane, plus the darkening of the surface resulting from pools of water, makes it increasingly unlikely that they will spontaneously refreeze – to do so would require a sustained return to a much cooler climate. Another example, which has been suggested, is the susceptibility of tropical rainforests to fire if they experience prolonged dry spells. Once the forest burns, the canopy is opened up, favoring the growth of grasses, which in turn makes future fires more likely. These examples are elaborated below.

4.09.3.3 The Hypothesis of Terrestrial C Sink Saturation

The likely presence of thresholds can sometimes be predicted from a qualitative knowledge of the form of the interactions in a system. For instance, both heterotrophic and autotrophic respirations increase with rising temperature. The relationship is conventionally represented by an exponential function. Furthermore, the respiration rate is more or less proportional to the soil carbon and biomass pools, respectively. The global mean temperature, over multi-year timescales, is approximately proportional to the global atmospheric CO_2 concentration. On the carbon uptake side, photosynthesis on land is a saturating function of atmospheric CO_2 and a hump-shaped function of temperature with a peak below 30 °C. Scholes (1999) and Kirschbaum (2000) both speculated that the consequence of this set of interactions would be that the land would initially be an increasing carbon sink, as photosynthesis rose in response to rising atmospheric CO_2 concentration. The sink would peak and then decline (eventually becoming a net source) as respiration, in response to rising temperature and accumulating C stocks, caught up with and overtook photosynthesis.

There is a second reason to expect the terrestrial biosphere to behave initially as a sink, but later to become a source, before returning to approximate neutrality. The time lags intrinsic to the terrestrial carbon cycle – the life span of a tree, for instance, or the turnover rate of soil carbon – means that there is inevitably a delay between photosynthesis and respiration, since the carbon must first be captured before it can be respired.

Subsequent detailed quantitative and spatially explicit modeling efforts have tended to substantiate these qualitative predictions (Canadell et al. 2007). Most global climate models with a global C cycle model suggest that the current net global terrestrial carbon sink could peak in the twenty-first century and then decline, in some cases smoothly to a new equilibrium between respiration and uptake, but more often with some overshoot in favor of respiration (Friedlingstein et al. 2006). Carbon in the 'fast turnover' soil pool has a higher temperature dependency than more 'passive' soil carbon, and it is the increased turnover of this labile soil carbon, which contributes to the sink saturation rather than the release of recalcitrant carbon from the 'slow' pools (Fang et al. 2005; Knorr et al. 2005).

4.09.3.4 A Plausible Amazon Drought Tipping Point

One of the possible 'inevitable surprises' (Lenton et al. 2008) on the IPCC short list of plausible abrupt climate change scenarios (Solomon et al. 2007) is modification to the extent, structure, and behavior of the rainforest in the Amazon Basin. A combination of changes in tree fraction, regional rainfall, and summer temperatures, due to a complex interplay between land use change, and anthropogenic and natural climate forcing is simulated, which in some models induces a partial dieback in the Amazonian rainforests (Cox et al. 2000, 2004; Betts et al. 2004; Malhi et al. 2009).

The majority of precipitation in the Amazon basin is recycled, e.g., it originates from water vapor evaporated in the basin itself. Therefore a change in the land surface – deforestation, or shift to more savanna-like species – could in principle lead to a positive feedback in the water cycle of the region (**Figure 4**). Modeling results hypothesize that dry-season water stress could increase in the twenty-first century, promoting a climate, which supports a seasonally deciduous forest (Malhi et al. 2009) or an open woodland with grasses (Betts et al. 2004; Cox et al. 2004), rather than the present evergreen forest. Such a state change could further reduce regional rainfall due to a reduction in hydraulic redistribution (Lee et al. 2005) and increase the regional temperature. It would also release CO_2 to the atmosphere. Higher atmospheric CO_2 also leads to stomatal closure, further reducing evaporation and ultimately, precipitation Costa and Foley (2000). Higher temperatures and reduced rainfall lead to reductions in NPP (Betts et al. 2004; Cox et al. 2004), and make the biomass carbon in the replacement seasonal forests vulnerable to fires (Malhi et al. 2009). Rainforest trees seldom experience fire and are therefore susceptible to fires in the litter layer and the near-ground vegetation. Generally the ground vegetation is kept sparse by the closed tree canopy and the litter layer is too wet to burn. A dry spell lasting several months can dry out the litter layer. If land clearing activities damage the forest margin, allowing fire in, the canopy trees can be killed, which lets in light, allows grasses to spread, and makes future fires more likely. A further feedback on rainfall could occur through the increased number of aerosols and cloud condensation nuclei produced by burning (Andreae et al. 2004).

4.09.3.5 Permafrost Melting

Estimates of the size of the carbon stocks in permanently frozen (permafrost) soils vary from 200–800 Pg C (excluding wetlands; Gruber et al. 2004), 400 Pg C (northern hemisphere only, Tarnocai et al. 2009), 900 Pg C (Zimov et al. 2006) to 1672 Pg C (in the northern circumpolar permafrost zone, including 277 Pg in peatlands (Schuur et al. 2008).

Schuur et al. (2008) show that permafrost thawing is not just driven by increased air temperature causing CO_2 release due to temperature sensitive decomposition. It includes other energy balance and physical processes (**Figure 5**). In thawing areas where ground-ice content is high, the risk of regional carbon loss through soil subsidence (thermokarst) and erosion increases (Schuur et al. 2008). While the heterogeneity and adaptiveness of soils makes the parameterization of turnover times a nontrivial task (Knorr et al. 2005; Davidson and Jassens 2006) we know that an increase in the rates of thawing and warmer soil temperatures would result in greater heterotrophic respiration. Assuming a temperature increase of 2 °C, up to 5 Pg C could be released from melting permafrost over a period

of 20 years, and up to 100 Pg C over 100 years (Gruber et al. 2004). Therefore, the vulnerability of permafrost carbon stock to temperature increases is potentially the most important feedback of terrestrial carbon within the climate system.

4.09.4 Vulnerability of the Terrestrial Climate Regulation Service to Climate

Here we follow the conventional vulnerability assessment approach, which considers vulnerability to be the product of exposure to a threat, sensitivity to that threat, and (lack of) capacity to adapt to the threat. We will consider adaptive capacity within a resilience framework that does not restrict the adaptations to those which keep the system more or less as it was, but allow it to transform to new states.

One 'threat' is surface temperature increases in conjunction with either increasing or decreasing water stress, depending on the region. Equally important are the accompanying changes in the probability of extremes of heat and cold, flooding or drought, and the changes in disturbance regimes which they can trigger (Field et al. 2012). Indirect effects include changes in the exposure to pests, diseases, and fire. Surface temperature change is just one of a series of environmental effects, such as rising CO_2, nitrogen and sulfur deposition, land management practices, and declining biodiversity. Exposure to this syndrome of stresses is spatially variable, but no part of the terrestrial biosphere is immune from them.

In evaluating 'sensitivity' we have drawn on two ideas developed above, the form (shape) of the relationship, and the sign and strength of any feedbacks that exist. Sensitivity is low if a change in the 'threat' parameter produced a much less than proportionate change in the outcome of an affected system, and high if the effect is more than proportionate. A concave functional response (one that becomes progressively steeper as the size of the driving threat increases) is initially insensitive, but becomes highly sensitive beyond some point. Convex or saturating functions, on the other hand, become progressively less sensitive. A threshold response is one with an abrupt point at which they become sensitive. Sensitivity needs to be explored over timescales of decades to centuries, given that many of the processes are gradual and the pools can be long-lived (Table 1).

Several approaches have been applied to evaluating the sensitivity of carbon fluxes and pools to climate. Gruber et al. (2004) used a risk-assessment approach incorporating expert opinion. The C^4MIP experiment (Friedlingstein et al. 2006) used complex climate models with a carbon cycle. Raupach and Canadell (2008) used a less numerically intensive 'perturbation-based approach' in which they compare the effects of a disturbance in coupled and uncoupled semiquantitative models.

Figure 5 Permafrost melting includes direct and indirect feedbacks involving physical changes to the soil column, changes in surface brightness and fire. Summarized from Schuur, E. A. G., and Coauthors, 2008: Vulnerability of permafrost carbon to climate change: implications for the global carbon cycle. *BioScience*, **8,** 701–714.

4.09.4.1 Fire

Variation in the areas burned is responsible for a significant part of the variation in the annual CO_2 balance (van der Werf et al. 2006). Over a course of season, year, or longer term depending on the ecosystem, the terrestrial carbon losses from fires are generally compensated for by gains in biomass as vegetation regrows following a burn, but if changes in land use, land management, or climate affect the frequency or intensity of fires, the recovery may be less than complete, or overcompensate. It is during such periods of regime transition that long-term trends in carbon accumulation change from net uptake to net release, or vice versa (Raupach and Canadell 2008).

Fire can occur in almost all terrestrial biomes, but the current extent of fires and the quantity of carbon consumed are concentrated in the tropical savannas and the boreal forests (van der Werf et al. 2010). The area burned in savannas annually is very large, but the fires consume relatively little fuel per unit area, since they burn mostly dry grass, leaving the trees intact.

Boreal forests are one of the largest world biomes. Some estimates have them storing over one-third of terrestrial biospheric carbon, particularly in the form of forested peatlands (Kasischke et al. 1995). Approximately two-thirds of the boreal forests lie in the Russian Federation, with the rest falling mostly in Canada and Alaska (Wooster and Zhang 2004). The landscape is a matrix of different forest types, each storing differing amount of carbon. Together with differences in the severity of the fire, this affects the total direct carbon emissions from fires in boreal forests by as much as 50%. The emissions in extreme fire years are 37–41% greater, due to soil organic matter combustion (Soja et al. 2007). The probability of more fire in boreal forests in the future is high (Achard et al. 2008), with consequences for the global carbon cycle (Conard and Ivanova 1997; Soja et al. 2007).

4.09.4.2 Heatwaves

Episodes of above average temperature with or without below average rainfall have the potential to significantly alter carbon fluxes and stocks. For example, Europe experienced a heat wave in the summer of 2003, with July temperatures up to 6 °C above long-term means and annual precipitation deficits up to 300 mm year^{-1}, about 50% below the average (Ciais et al. 2005). A significant reduction in gross primary productivity (GPP) was experienced throughout the continent (Ciais et al. 2005). The productivity of the temperate forest and grasslands ecosystems (Ciais et al. 2005; Granier et al. 2007) and croplands (Granier et al. 2007) Europe-wide was affected. A dramatic reduction in crop yield occurred in France, Italy, and south Germany. Tree radial growth was reduced especially in the year following the drought (Granier et al. 2007).

Both autotrophic and heterotrophic respirations were controlled by water availability to varying degrees across Europe (Grainer et al. 2007). Although 2003 is not the driest year on record, the impacts of the water stress was amplified by the high summer temperatures and soil water deficits carried

Table 1 A classification and evaluation of vulnerabilities, based on the expert opinion of the authors, informed by a review of the literature. For a definition of terms, see the text

Driver of change ('Threat')	*Affected system*	*Sensitivity and form of relationship*		*Adaptive capacity*	*Vulnerability outcome*
Changes in surface temperature	Carbon in non-wetland, non-frozen soils	High and concave		Microbial communities change, but respiration still increases with increased temperatures	High
	Carbon in permafrost soils	Very high and controlled by a threshold		None	Very high
Increasing or decreasing water stress	Wetland soils (peats)	Convex for further wetting of wet systems, threshold for drying below limit for wetland persistence		Loss (or gain) of C compensated by decrease (increase) in CH_4 emission	Medium
	Net primary production	Linear, with a threshold for extreme droughts		Results in long-term species composition shifts but NPP remains affected. Higher diversity helps	Medium
Extreme wind and rain events	Forest biomass	Threshold effect where winds exceed bending or root strength tolerance		High recovery in systems with a history of exposure, occurs through succession	Low

Fires	Biomass, especially of trees, and litter layers or peat	Threshold effect for unadapted systems, concave for adapted systems	 	Replacement by fire-adapted vegetation, but net reduction of stored C	High
Pest outbreaks	Biomass and net primary production	Concave, thresholds for some pests; interaction with fire	 	Long term re-equilibration between predators and prey. Higher diversity may help	Medium
Land use change	Soil and biomass C	High, often a threshold effect use type changes rather than use intensity		High adaptive capacity through policy (e.g., REDD) and innovation	High
N and S deposition	Tree biomass	Hump-shaped curve – initial stimulation, depression at high cumulative levels		Long-lasting ecosystem function, composition and structure changes. Technological adaptive capacity to reduce deposition	Medium

over from the previous spring (Ciais et al. 2005). Because both GPP and the respiration fluxes were reduced, the absolute decrease in NEE was smaller than the reduction in GPP (Ciais et al. 2005; Grainer et al. 2007). The consequence for the net carbon balance was that European temperate forests became a strong net source of carbon dioxide (0.5 Pg C year^{-1}), which reversed the effects of four preceding years of net ecosystem carbon sequestration (Ciais et al. 2005).

An analysis of the northern hemisphere terrestrial carbon fluxes shows that since 1994, the enhanced carbon uptake due to a progressively earlier spring has been canceled by decreased uptake during summer, due largely to hotter and drier summers in the mid and high latitudes (Angert et al. 2005). Enhanced productivity with warmer temperatures and longer growing seasons might be counterbalanced by more frequent heat and drought events. Thus, although the forests of the world currently constitute a large sink (Yude et al. 2011), the reliability of this sink under hotter, sometimes drier, more variable climates could be spatially and temporally more variable.

4.09.4.3 Increases in Rainfall, Decreases in Rainfall, and Prolonged Droughts

The interannual variability of the growth in atmospheric carbon dioxide is largely due to variability in the terrestrial term. Most of that variability is located in the tropics, a large fraction of which is in Africa. The variation is strongly associated with climate indices such as ENSO. It is inferred that much of the variation is due to the source or sink behavior of the tropical season savannas rather than the continuously moist evergreen rainforests. A multi-year record of carbon fluxes exists for the flux station at Skukuza in South Africa that supports this argument. The site is a carbon sink during wetter-than-average years, and a source during drier than average years. Overall, over the period of record, it has been a source (Archibald et al. 2009a).

A disproportionate part of the interannual variation in Fraction Absorbed Photosynthetic Radiation (FAPAR) in this mixed tree-grass system is due to the grasses. As has been observed in other savannas, the tree leaf area duration varies little from season to season, but the grass leaf area is highly dependent on rainfall (Archibald and Scholes 2007). Contrary to conventional wisdom, the area burned in African savannas and the amount of biomass consumed by fire both decrease in dry years, because the available fuel decreases (Archibald et al. 2009b).

4.09.4.4 Windstorms

Windthrow of trees is one of the most common disturbance dynamics in forests. An example involving a tropical hurricane in Puerto Rico is described by Walker (1991) and its carbon cycle consequences are explored by Sandford et al. (1991). They found a net release of carbon dioxide resulting from the loss of foliage and the increase in the litter and dead wood pools, but a relatively rapid return to net sink status as the rapidly growing trees establish a complete cover. Long-term simulations suggest that the forest can continue to be a net sink of carbon, on average, even with a major hurricane disturbance once a century.

Knohl et al. (2002) measured carbon exchange from an area of Siberian temperate forest 2 years after a major storm disturbance. They found a daytime sink, but a larger respiration source once the nighttime fluxes were added. From the quantity of downed timber and the observed log decay rate, they concluded that the storm event would have consequences for the carbon balance of the site for decades. Kramer et al. (2004) followed the carbon dynamics across wind-disturbed stands of various ages in Alaska and found remobilization and transport of carbon between fractions in the soil and vegetation.

These examples suggest that carbon stores are relatively robust to windthrow disturbances, but if the frequency of severe windstorms were to increase, the mean landscape stored carbon would be somewhat reduced.

4.09.4.5 Insect Attacks

The impact of insects on forest carbon dynamics is not only felt through the reduction in carbon uptake due to canopy loss, but also through increases in future carbon dioxide emissions from the decay of the killed trees (Kurz et al. 2008). In western Canada, the unprecedented severity and extent of the Mountain pine beetle (*Dendroctonus ponderosae*) outbreak experienced over the last decades has been attributed to two major factors: (1) a larger extent of suitable pine hosts due to forest stand maturation and (2) an expanded distribution range of the Mountain pine beetle due to warmer and drier weather (Kurz et al. 2008).

4.09.5 Ways of Reducing Vulnerability

Vulnerability can in principle be reduced by addressing any of its three components: reducing the level of the threat; reducing the sensitivity of the system; or increasing the adaptive capacity. Reducing the threat, for instance, requires policy approaches to minimize the impact of human climate forcing on the climate system (e.g., Metz et al. 2007; Pielke 2010), since the scope for reduced sensitivity and increased resilience has limits: mitigation efforts must be sufficient to keep the terrestrial biosphere within an adaptable domain. The following broad classes of actions have been proposed as ways of reducing sensitivity or increasing resilience.

4.09.5.1 Preemptive Microdisturbances

A hypothesis of resilience theory (Gunderson and Holling 2002), paraphrased in the context of carbon storage, is that systems cycle through phases of accumulating biomass and connectivity, leading to increased vulnerability, collapse, reconfiguration, and rebuilding. The implication is that these are inevitable phases, but the rate of progression through them could be manipulated by management. One approach is to deliberately initiate small destruction–reorganization cycles during the accumulating phase, in order to extend it and preempt a catastrophically large reorganization. In some ways this is similar to the ‘intermediate disturbance hypothesis’ (Connel 1978), which suggests that biodiversity and ecosystem function are maximized neither under a zero disturbance, nor under a maximal disturbance regime, but under some intermediate regime. A practical example is the use of small, frequent fires in forest or woodland management to prevent the build up of fuel that would eventually lead to a large fire that consumed more biomass in total, or damaged the capacity of the system to recover (Richards et al. 1999; Beverley et al. 2009).

4.09.5.2 Maintaining Ecosystem Function and Biodiversity

Preserving the integrity of ecosystem processes has been suggested as a necessary condition for maintaining both the buffering capacity of ecosystems (e.g., reducing sensitivity) and adaptive capacity (e.g., Smithers and Smit 1997). It is often inferred that maintaining biodiversity (in its broad sense – not only what species are present, but their relative abundances and within species genetic variability, as well as the landscape-scale structural, compositional, and functional diversity of ecosystems) is a proxy ecosystem integrity. The exact links between the various aspects of biodiversity and the dimensions of ecosystem function remain unclear, but there is empirical evidence that they exist (Zavatela et al. 2010). They may account for only a portion of adaptive capacity and buffering, may relate more to the diversity of functional groups rather than species per se, and are likely to be saturating functions, which level off at levels of biodiversity substantially below the maximum (Díaz et al. 2005).

4.09.5.3 Reducing Vulnerability to Social Change

It is increasingly indefensible to regard ecosystem change as divorced from social change. In reality they are intimately linked as social–ecological systems (Folke 2006; Chapin, this volume). Very frequently the change dynamics are initiated within the human part of the system, or the feedback processes operate via the human system. Land use change, leading to land cover change, is a major vulnerability of soil and biomass carbon (Marland et al. 2003). It is principally controlled by demographic, political, and economic factors (Lambin et al. 2001), but there may in the century timescale be climate feedbacks, as areas formerly suitable for certain uses become unsuitable, and new areas become suitable. The key vulnerability reduction actions are related to policy: what land uses may be practiced, who has rights to practice them and with what security of tenure; who pays for externalities such as those due to human climate forcing; and what prices (including subsidies) are paid for the various land-based commodities. The general recommendations for increasing the resilience of social-economic systems involve creating a sense of local ownership, stewardship and reward, effective multiscale participatory governance, and enhancing adaptive capacity through leaning and innovation (Berkes et al. 2003).

4.09.5.4 Dealing with Vulnerability in the Climate Service Market

The discussion which follows is not about reducing the fundamental vulnerability of land-based climate regulation services, but on how to establish a viable market-based service for carbon in the presence of that vulnerability. In particular, it addresses the problem of the impermanence of stored carbon on land.

There are two main approaches. The first is based on portfolio theory. By increasing the scale of projects, including different types of projects that are assumed to have uncorrelated risks, and taking to market a service that is smaller than the total amount within the portfolio, it is possible to reduce the variability of carbon services product below the fundamental variability of the service at any given location (Laurikka and Springer 2003).

The second approach is to treat the climate service as a renewable short duration contract, rather than a permanent asset. In other words, the client rents the service on a year-by-year basis for as long as it persists, rather than purchasing it outright. This is consistent with the observation that the terrestrial carbon storage service is a flux (a change in stock) rather than a stock itself. This is the logic behind the field of PES, of which REDD is a specific example relating to the climate service and also to biodiversity and other ecosystem services (Kindermann et al. 2008).

4.09.6 Trade-Offs between Climate Regulations and Other Ecosystem Services

When single-mindedly maximized, provisioning services (such as carbon sequestration) occur at the detriment of competing provisioning services, most regulating services, and sometimes cultural services (Millennium Ecosystem Assessment 2005). For instance, if a monocultural tree plantation were established in a formerly biodiverse and water limited area, the river flow would decrease, and biodiversity would be lost, as would the opportunity to grow other crops or to graze the land. If maximum stored carbon were the goal, the production of timber from the plantation would be reduced.

Such stark, mutually exclusive trade-offs are not inevitable. It is usually possible to get some level of climate service from a landscape without completely compromising other land use objectives. There are even cases of synergy, where management for the climate regulation service is also beneficial for other services. For example, the REDD+ notation suggests that protection of the climate regulation service provided by tropical forests can also confer biodiversity, water, and livelihood benefits.

4.09.7 Conclusions

The climate regulation service provided by terrestrial ecosystems is real and substantial. It occurs through a variety of mechanisms, whose relative importance varies from place to place. The carbon storage mechanism at global scale has increased over the past few decades, largely through autonomous mechanisms (in other words, not as the result of deliberate human actions). The terrestrial carbon sink cannot continue to grow indefinitely. There are several feedback processes, which may cause it, perhaps within decades, to change from a sink at the global scale to a net carbon source, even though at local or regional scale some areas may remain as sinks.

The terrestrial carbon storage service is in general relatively vulnerable, both to climate itself and to associated environmental change factors such as changes in fires, windstorms, and pest outbreaks. It is also vulnerable to economic and political factors, which may or may not be linked to climate. The magnitude of the carbon storage service can be moderately increased at local scale through management actions, and at regional and global scale through policy decisions, but doing so tends to increase the vulnerability of the service. The vulnerability of the service can probably be significantly reduced, but not eliminated through a combination of management and policy actions.

4.10.1 Introduction

Earth's climate is moderated by coupled cyclings of carbon (C), nitrogen (N), water (H_2O), phosphorus (P), and sulfur (S). Perturbations of these cycles, by natural or anthropogenic forces, can alter Earth's climate. It is the anthropogenic disturbance of the C and N cycles, through land use and fossil fuel combustion, which has increased the risks of changes in climate statistics. Mitigation of and adaptation to environmental changes necessitate enhanced understanding of the processes, causes, and factors that control vulnerability of an ecosystem to the combined effects of environmental change drivers. Sources and drivers of these changes must be known and prudently managed.

4.10.1.1 Agroecosystems and Sources of Anthropogenic Emissions

There are two principal sources of anthropogenic emissions: land use conversion and fossil fuel combustion. Conversion of natural ecosystems to agricultural land commenced with the dawn of settled agriculture about 10–13 millennia ago. Ruddiman (2002) hypothesized that drastic anthropogenic changes occurred by the onset of forest clearance about 8000 years ago and with cultivation of irrigated rice paddies and domestication of livestock about 5000 years ago. The C flux through land use change from prehistoric times to 2000 has been estimated at 480 Pg by Ruddiman (2003) and 262 Pg by Olofsson and Hickler (2008). The latter estimate was comprised of 114 Pg during the preindustrial time and 148 Pg since the industrial era between 1850 and 1990. Olofsson and Hickler (2008) estimated that 90% of the C emission from land use conversion occurred after AD 1. Between AD 1 and 2000, a large number of natural ecosystems (forests and savannas) have been converted to cropland and pastureland (**Table 1**). Gaseous emissions from combustion of fossil fuel drastically increased between 1750 and 2000. Whereas the contribution of land use to atmospheric C exceeded that of fossil fuel combustion until late 1950s or early 1960s, the relative magnitude of emission by land use has progressively decreased. The data in **Table 2** show that the ratio of CO_2–C emission from fossil fuel combustion (plus cement production): land use was 2.1 in 1960s, 3.6 in 1970s, 3.7 in 1980s, 4.0 in 1990s, 5.5 in 2000s, and 7.3 in 2008. To date, the cumulative amount of CO_2–C emission is about 300 Pg from both land use and fossil fuel combustion (Archer 2009). The anthropogenic transformation of terrestrial biomes has been drastic between 1700 and 2000 AD. In 1700, about 50% of the terrestrial biosphere was wild, and 45% of the remainder was in a seminatural state. By 2000, the majority of the biosphere was under agriculture and urban settlement and <20% was seminatural (Ellis et al. 2010). Increase in human demands, especially the production of food, has been the principal driver of this transformation.

4.10.1.2 Ecosystem Services

Rather than a gradual change to which the ecosystems can adjust, extreme climate events or abrupt climate changes can cause severe disturbance of ecosystem functions and services. Ecosystem services represent the benefits that people (and

other biota) obtain from ecosystems. The specific benefits vary among ecosystems or biomes. Thus, assessment of these benefits necessitates formulation of indicators that may differ among diverse ecosystems. It is also important to establish baselines (Perrings et al. 2011; Kumar 2010), against which to measure the changes in ecosystem services. The Millennium Assessment (2005) project estimated that 60% of the services or societal benefits provided by biomes have been diminished through human activities since the 1950s. Consequently, the boundaries of natural biomes are being redrawn (Alessa and Chapin 2008) and the drastically altered biomes are called Anthromes. Sustainability of these systems is vulnerable to the multitude of stressors generated by human activities as these affect energy/nutrient transfer along food webs and the cycling of water and elements (i.e., C, N, P, S). These anthromes must now provide the ecosystem services needed to sustain human societies, and crops obviously have a major role in this activity.

Crops are planted to provide 'provisioning services' (see Chapin et al. 2009), but the consequences and potential change in other ecosystem services related to climate (e.g., supporting and regulating services) is equally large. Land use and land cover change is a major player affecting regional climate characteristics (Pielke et al. 2011; Pitman et al. 2011; Avila et al. 2012). Agroecosystems have profound effects on local and regional climates via their ability to alter energy returns to the atmosphere. As noted by Baldochi (this volume), agroecosystems have reflectivity (albedo) values that are often different from native vegetation found in similar areas. Higher albedos can reduce surface warming, and the importance of increasing crop albedos has become a legitimate science question (e.g., Ridgwell et al. 2009). More importantly, crops are usually designed to exploit soil moisture, such that energy captured by evapotranspiration (latent heat) can also be higher than in native vegetation, and with irrigation, the percentage of net radiation that is transferred back to the atmosphere in water vapor can be very high. This water vapor can be returned as rainfall (e.g., Pielke et al. 2007). Thus, agricultural systems have the potential to mitigate surface temperatures and can potentially increase rainfall, particularly if irrigation is applied and mechanisms exist to deliver moist air to the atmosphere. Thus, the extent of agroecosystems across terrestrial surfaces and the specific crop and management scheme used on these lands have large effects on climate and have the potential to be used as a mitigation factor.

Extreme events can lead to changes in ecosystem services (Breshears et al., 2011). For example, drought-induced tree die-off and the increase in risks of fire in semiarid woodlands and grasslands can severely disrupt services provided by these ecosystems. It is widely hypothesized that extreme events exacerbate risks of wild fires (Pederson et al. 2010; Bowman et al. 2009), tropical storms, and the attendant large floods (Overpeck and Cole 2006) such as in Thailand in 2011, droughts (Wilcox 2010), such as in Texas in 2011, tourism and fisheries (Pederson et al. 2010).

The Anthropocene era, through drastic transformation of Earth's biomes and by fossil fuel combustion, has altered the atmospheric chemistry and increased the concentration of greenhouse gases, as well as converted vast regions from their natural landscape type. The current climatic conditions, as a result of these human disturbances, have exacerbated the vulnerability of ecosystems that were already transformed by other anthropogenic activities. Thus, the objective of this chapter is to deliberate the vulnerability of terrestrial agroecosystems to possible changes in the coming decades and to establish the cause–effect relationship between land use and climate.

4.10.2 Food Security

The issue of food security, for the growing and increasingly affluent population, is both the cause and the effect of the anthropogenic activities. It is the ever-increasing human demands for food, feed, fiber, and fuel that are driving the transformation of Earth's biomes and additional need for land to meet these demands (Bruinsma 2009; Clay 2010). There is a need to critically and objectively rethink food security for the 21st century (Falcon and Naylor 2005). In addition to the overview provided here, readers are urged to see the recent volume focusing on climate vulnerabilities of food resources edited by Niyogi (2013).

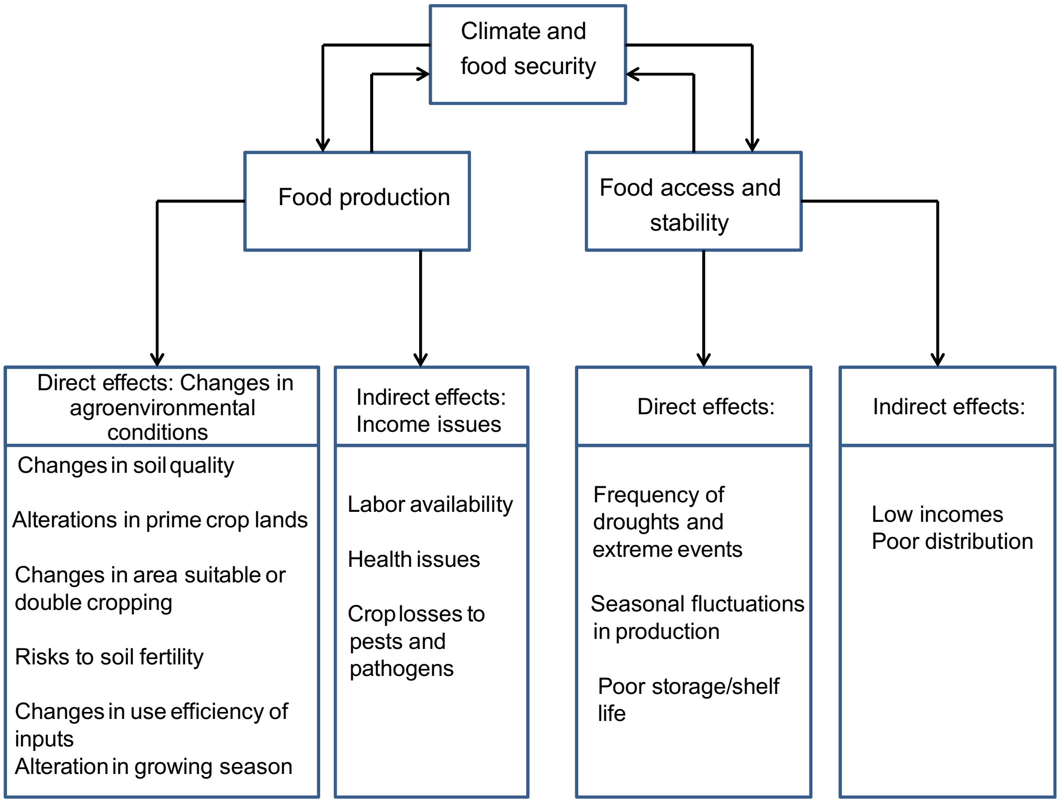
4.10.2.1 Food Demand

The doubling of agricultural production between 1965 and 2000 by adoption of the Green Revolution technologies was brought about through increases in inputs by 7 times for nitrogenous fertilizers, 3.5 times for phosphatic fertilizers, 1.7 times for the irrigated cropland area, and 1.1 times increase in the arable land area (Tilman 1999). Since 1970, crop production has more than doubled, although cropland area has increased by only 12% (Foley et al. 2007). The nitrogenous fertilizer, produced by the Haber–Bosch process of converting inert atmospheric N_2 into reactive NH_3, has made it possible to feed an additional several billion people. Without these fertilizers, it would take substantially more cropland than 1.5 billion hectares currently used for cultivation. Such large areas simply do not exist. Thus, the projected 70% increase in food production between 2010 and 2050 will necessitate additional use of fertilizer inputs and also some expansion in the arable land area. The long-term chemotherapy of agricultural land, by use of fertilizers and pesticides, has altered both structure and functions of agroecosystems. Soil and climatic measurements indicate that the global annual average surface air temperature has warmed by about 0.8 ± 0.2 °C since 1850 (The Royal Society 2010), and continued increases are a plausible scenario (IPCC 2007). Intensive food production will further aggravate emission of greenhouse gases and drastically alter the terrestrial and aquatic biomes. Anthropogenic emissions, by land use conversion and fossil fuel combustion, are estimated to have increased global temperatures by ~0.13 °C/decade since 1950, with similar increases possible over the next few decades (IPCC 2007; Lobell et al. 2011). As seen to date, local and regional responses, however, will considerably vary. Moreover, a global annual average surface temperature does not capture the actual temperatures experienced across the diverse croplands.

The term food security implies four key dimensions: availability, stability, access, and utilization (FAO 2010). Both current and plausible future climate can adversely affect stability of food supply and its access to vulnerable population because agriculture is not only a source of food but also of the income for small land holders and resource-poor farmers from around the world (Schmidhuber and Tubiello 2007). Direct and indirect effects of climate on food security are outlined in **Figure 1**. The direct effects are those that alter production and may be positive or negative. Whereas the possible negative effects are widely discussed in scientific and popular media, there may as well be some opportunities created by alterations in regional and local climatic conditions that must also be identified and harnessed. The indirect effects are those that may alter food access and stability by changing income, distribution, and post-harvest losses (**Figure 1**). The exact magnitude and direction (positive or negative) are difficult to generalize. Through adaptive and coping strategies, discussed in Section 4.10.4, the goal is to accentuate the positive and minimize the adverse or negative effects.

More than one billion people are vulnerable to food insecurity (Barrett 2010), and the number may increase because of the possible decrease in cropland area by 110 million hectares (Mha) in developing countries located in the lower latitudes (Schmidhuber and Tubiello 2007). Shifts in the growing season may lead to declines in the land area suitable for double cropping in some areas but could increase this potential elsewhere. In addition, water limitation and droughts strongly reduce crop yields and livestock productivity. Vulnerability to climate-induced food insecurity may be more severe for small land holders who practice subsistence agriculture (Morton 2007). It is defined as "farming and associated activities which together form a livelihood strategy where the main output is consumed directly, where there are few if any purchased inputs, and where only a minor proportion of output is marketed" (Barnett 1997). Similarly, small-holder agriculture refers to "rural producers who farm mostly by family labor and for whom farming is the principal income source" (Cornish 1998). Despite numerous constraints, subsistence and small land holders have inherent advantages to cope with a subset of climate-induced stresses. Important among these advantages are high labor efficiency, large livelihood diversity, and benefits of indigenous knowledge (Morton 2007). These characteristics have evolved over generations and, thus, have high adaptability and built-in coping strategies toward climate variability and other biotic and abiotic stresses.

Drought-related adverse effects of climate on food-security are also caused by excessive heat during the growing season (Battisti and Naylor 2009). The crop yield gap, the difference in



Climate and food security
Food production
Food access and stability
Direct effects: Changes in agroenvironmental conditions
Changes in soil quality
Alterations in prime crop lands
Changes in area suitable or double cropping
Risks to soil fertility
Changes in use efficiency of inputs
Alteration in growing season
Indirect effects: Income issues
Labor availability
Health issues
Crop losses to pests and pathogens
Direct effects:
Frequency of droughts and extreme events
Seasonal fluctuations in production
Poor storage/shelf life
Indirect effects:
Low incomes
Poor distribution

Figure 1 Direct and indirect effects of climate on food security.

Table 3 Existing yield gap for principal food crops in developing countries

		Yield gap	
Crop	*Country/region*	*Mg (yr^{-1})*	*Average yield (%)*
Wheat	Mexico-Yaqui Valley	5.8	41
Wheat	Bangledesh	2.9	45
Wheat	Northern India	4.5	150
Rice	India	2.3	64
Rice	China	5.9	29
Rice	Indonesia	5.3	21
Rice	Thailand	4.0	32
Rice	Philippines	3.4	85
Maize	South Asia	1.4	690
Maize	Sub-Saharan Africa	0.7	543
Maize	Latin America Highlands	4.0	150

% Gap = [(potential yield – average yield)/average yield] × 100.
Adapted from Lobell, D. B., K. G. Cassman, and C. B. Field, 2009: Crop yield gaps: their importance, magnitudes and causes. *Annu. Rev. Environ. Resour.*, **34**, 179–204.

attainability, and the national average crop yield (Hengsdijk and Langeveld 2009; Lobell et al. 2009) are large for subsistence and small land holders of developing countries (Tables 3 and 4). For example, the yield gap (%) for wheat is 150 in northern India and 41 in Yaqui Valley, Mexico, that for rice is 64 in India and 21 in Indonesia, and that for maize is 690 in South Asia and 150 in Latin America (Table 3). The yield gap (%) for rice is 13 in Northeast Asia and 575 in humid Arica, that for maize is 7 in western Europe and 506 in humid Africa, and that for tropical cereals is 867 in South Asia and 986 in semiarid Africa (Table 4). The yield gap has been more highly influenced than has been the climatological average temperatures during the growing season, and by any increase in drought and other extreme events. Indeed, the climate is a severe threat to global food security.

4.10.2.2 Required Crop Yield in Developing Countries to Meet the Food Demand

Much of the food production growth between 2010 and 2050 must come from increase in productivity per unit area and use efficiency of inputs. Some inputs essential to enhancing productivity of grain crops include fertilizers and irrigation. Based on all inputs involved, the required yields of three food crop staples must be increased in all developing countries between 2005–07 and 2050 by as much as 60% for wheat, 49% for rice, and 55% for maize (Table 5). With large footprints for irrigation and the associated energy requirements (Khan and Hanjara, 2009) along with threats to human water security (Vörösmarty et al. 2010), supplemental irrigation is a major uncertainty for many areas. The projected slow trend in cereal yields increase in developing countries from 1961–63 to 2050 range from 2.2 to 0.8%/yr (Bruinsma 2009). Thus, the importance of irrigated agriculture in moderating the yield increase cannot be overemphasized. There has to be a rising share of increase in yield through irrigation, especially in China, India, and other developing countries. The data in Table 6 indicate the required increase in yield of cereals in the world and in developing countries with and without irrigation. By 2050, it is estimated that grain yield of all rainfed cereals would have to be increased from 2.64 to 3.58 Mg ha^{-1} in the world and 1.97–2.80 Mg ha^{-1} in the developing countries. Thus, the total increase in rainfed cereal yield, in this scenario, would be ~36% for the world and ~42% for the developing countries. In comparison, the cereal yield of irrigated agriculture would be increased from 4.67 to 6.10 Mg ha^{-1} (31%) in the world compared with 4.39–5.90 Mg yr^{-1} (34%) in the developing countries. In comparison with the rainfed conditions, cereal yield with irrigation in the world and developing countries, respectively, was 76% and 123% in 2005–07 compared with the scenario increase of 70% and 111% by 2050. Moderate alterations in regional and local climatic conditions may also have some beneficial impacts in some regions across East Africa (Doherty et al. 2010).

4.10.2.3 Vulnerability of Cropland to Extreme Events

Climate can impact cropland by altering the risks to soil degradation and desertification (Geist and Lambin 2004) and the resilience of land that is potentially cultivable. Erosion is a major long-term threat to soil fertility and agriculture regardless of the presence of other drivers of soil change (Montgomery 2007). The risks of soil degradation by erosion (water and wind), salinization, and other processes may be exacerbated by extreme events (e.g., fire, drought, floods) and other climate related factors (Feddema and Freire 2001). Reduction in the vegetative cover by fire and the hydrophobic surface conditions thus created are known to cause flash floods and increase risks

Table 4 Yield gap of principal crops on regional basis

	Maize		*Rice*		*Tropical cereals*	
Region	*AY (Mg ha^{-1})*	*Gap (%)*	*AY (Mg ha^{-1})*	*Gap (%)*	*AY (Mg ha^{-1})*	*Gap (%)*
Caribbean/LA	3.5	186

of surface runoff and accelerated erosion (Gimeno-Garcia et al. 2007). Removal of vegetation cover, such as by overgrazing (Otterman 1974) or by inappropriate cropping management, can expose high-albedo subsoil and enhance vulnerability to desertification.

There is an estimated reserve of about 120 Mha of potentially cultivable land mainly in tropical South America and Africa. There may be a decrease in the suitability of these lands for cropland by climate shifts (Ramankutty et al. 2002). In contrast, however, there might be an expansion in cropland suitability in the northern hemisphere and high latitudes.

4.10.2.4 Carbon Sequestration in Agroecosystems and Soil Quality

Soils of agroecosystems (i.e., croplands, grazing lands) have a potential to sequester carbon (Lal 2004; 2010a) and offset anthropogenic emissions. However, surface temperature increases may alter the metabolic balance of agroecosystems, disturb the dynamic equilibrium between photosynthesis and respiration, and reduce the rate and magnitude of C sequestration in soil and the biomass. There exists a strong positive feedback between temperature and CO_2 emission due to an increase in rate of soil respiration (Melillo et al. 2002; Canadell et al. 2007; Arnone et al. 2008). Soil carbon sequestration is extremely sensitive to temperature regime (Davidson and Janssens 2006). While reducing the soil carbon pool, warming may also adversely impact soil quality and use efficiency of agroecosystems (Lal 2010b). The type of crop and how it is managed can have very large effects on surface temperatures and, therefore, be used to mitigate carbon sequestration (Lal 2008).

4.10.3 Water Security

Climate impacts water resources both directly and indirectly (Brian et al. 2004). Directly, it involves the amount type, timing and distribution of precipitation, and the frequency of extreme events. The direct effects are manifested through base flow, storm flow, flooding, and ground water recharge, as was the case in Texas during 2011. Changes in frequency and intensity of drought can adversely impact the water security including the availability of drinking water. The indirect effects of a temperature increase caused by land use changes (e.g., Fall et al. 2009), or other climate effects, on water security are partly due to the fertilization effect from CO_2 (especially in C_3 plants) and partly due to increase in plant water use because of increase in temperature. The latter increases both transpiration and evaporation, thereby decreasing the stream flow and the aquifer recharge. The combined direct and indirect effects, as influenced by nitrogen deposition and additional factors, may also alter the species composition over the long term (Sun et al. 2011).

Water security also depends on the ground water resources, which can be altered by the changes in precipitation. About 75% of the residents of European Union depend on ground water for their water needs (Klove et al. 2011). Irrigation of the rice-wheat system in the Indo-Gangetic Plains of South Asia also depends on the ground water. An important threat to the supply of ground water is through depletion (lowering) of the water table because of excessive withdrawal and lower recharge. This threat is driven both by human decisions as well as by climate. Environmental changes collectively alter the components of the hydrologic cycle (i.e., surface, runoff, base flow, soil water storage, evapotranspiration) and affect water security especially in arid and semiarid regions.

Changes in the hydrologic cycle can affect the river flow (Palmer et al. 2009) and thus affect water security. There is a strong link between food security and the availability of renewable fresh water resources. Reduced availability of good quality water for irrigating croplands that produce 40% of the world's food on just 18% of the irrigated area (Khan et al. 2009) is an example of the close link between food security and water security. Almost 80% of the world population is vulnerable to high levels of threat to water scarcity (Vörösmarty et al. 2010), and the threat is likely to be exacerbated in the future (Karl et al. 2009).

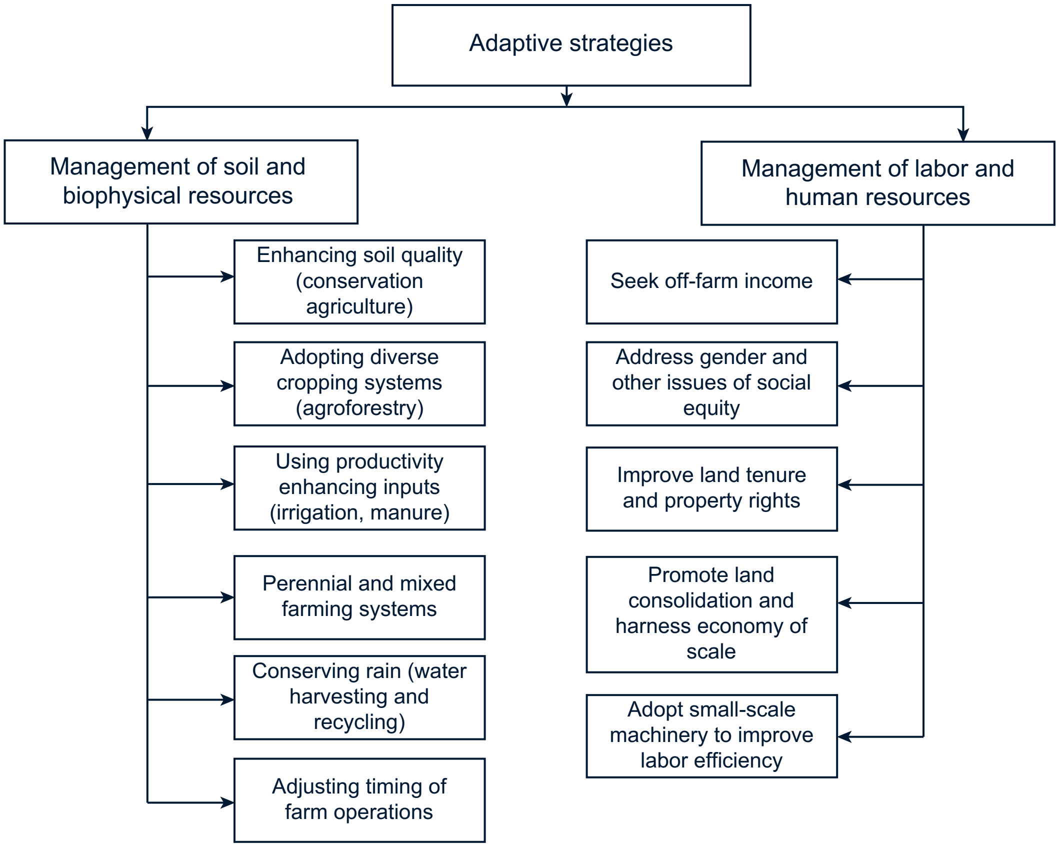
4.10.4 Adaptation of Agroecosystems to Climate

Principal ecosystem services provided by agroecosystems are food, feed, fiber, and fuel. Food security (see Section 4.10.2) will remain a major global issue until 2050 and beyond. The challenge of food security for 9.2 billion people by 2050 is enhanced by consumption growth and climate uncertainties. The increase in animal-based diet with an increase in per capita income may also aggravate the food insecurity (Keyzer et al. 2005). Lobell et al. (2011) estimated that between 1980 and 2008, global maize and wheat production declined by 3.8 and 5.5%, respectively, because of the change climate experienced during this time interval. Crop yield may also be reduced by increase in risks of soil erosion and the attendant loss of soil C that would also jeopardize soil quality (Ito 2007). The competition for land between production of food and biofuels may also aggravate food security (Raghu et al. 2011). Expansion of agroecosystems, conversion of natural biomes to croplands, and pasturelands would have profound effect on biodiversity and other ecosystem services (Green et al. 2005). However, agroecosystems can be managed to both mitigate and adapt to the spectrum of plausible future regional and local climates.

Agricultural ecosystems, already occupying 40–50% of the Earth's land surface, can be important and cost-effective soil C sinks. Thus, an active management toward recarbonization of the biosphere is an important option to affect future atmospheric CO_2 levels (Obersteiner et al. 2010). Important among these options for agroecosystems are restoring and reclaiming eroded and degraded soils and ecosystems, increasing soil C pool, conserving soil and water, and adopting farming systems that have high use efficiency of inputs. Considering all gases, the global technical mitigation potential (i.e., the removal of atmospheric CO_2) of agroecosystems by 2030 is estimated to be 0.4–0.44 Pg C/yr at C price \$20/Mg CO_2, 0.68–0.74 Pg C/yr at C prices of \$50/Mg CO_2, and 1.09–1.1 Pg C/yr at C price of \$100/Mg CO_2 (Smith 2011). These options are truly a win–win because of numerous cobenefits and deserve to be subjects of continued discussion.

In the context of adaptation, agriculture can be either based on the strategy of sustainable intensification by adopting land-saving technologies or it can be a nature-friendly system. Should agriculture be done to manage biodiversity or should biodiversity be preserved/protected through management of agriculture? There can be a trade-off between these two options (Green et al. 2005). Can 'climate-smart' agriculture advance food security and improve the environment (Pearce 2011). In the context of small land holders and subsistence farmers, adaptive and coping strategies are outlined in **Figure 2**. Sustainable management of soil and biophysical resources through adoption of recommended management practices (RMPs) is one option. Efficient management of labor and human resources through addressing the human dimensions is another (**Figure 2**). Both options are important to advancing food security and may differ among regions with different biophysical and social/economic/cultural factors.

It is generally argued that South Asia and Sub-Saharan Africa are two regions that may be prone to negative effects on food security without sufficient adaptation of appropriate measures (Lobell et al. 2008). However, the uncertainties about crop failure and severe yield reductions widely vary among crops, soils, and agroecoregions. While improving short-term options is important, it is also necessary to identify and implement long-term strategies that may include the following (Fazey et al. 2010): (a) addressing both the biophysical and the



Adaptive strategies
Management of soil and biophysical resources
Enhancing soil quality (conservation agriculture)
Adopting diverse cropping systems (agroforestry)
Using productivity enhancing inputs (irrigation, manure)
Perennial and mixed farming systems
Conserving rain (water harvesting and recycling)
Adjusting timing of farm operations
Management of labor and human resources
Seek off-farm income
Address gender and other issues of social equity
Improve land tenure and property rights
Promote land consolidation and harness economy of scale
Adopt small-scale machinery to improve labor efficiency

Figure 2 Adaptive and coping strategies by small land holders and subsistence farmers.

human dimensions (refer to Figures 1 and 2), (b) diversifying the adaptive and coping strategies, (c) strengthening human resources capacity to enable the adoption of required strategies, and (d) putting biofuels in the ecosystem services context (Gasparatos et al. 2011).

4.10.5 Policy Implications for Agriculture

For what are perceived as the most vulnerable regions due to a variety of physical and social stressors (i.e., South Asia and Sub-Saharan Africa), community-driven development may be an appropriate option (Agrawal et al. 2008). This option would entail involvement of local institutions comprising civic, public, and private organizations. These institutions are relevant to gathering and disseminating relevant information, resource mobilization and allocation, capacity building, networking, and providing leadership. Promotion of RMPs as adaptive and coping strategies can be enhanced and facilitated through payments for environmental or ecosystem services (PES). Important among these are increasing C sequestration in soils and biota, improving water quality and supply of renewable freshwater resources, enhancing biodiversity, etc. While not being a panacea, PES is an important strategy of incentivizing the land managers and farmers toward adoption of a restorative land use and RMPs (Wertz-Kanounnikoff et al. 2011). The strategy of PES can be effective in situations where RMPs have numerous cobenefits, land managers are direct beneficiaries, and there exists a strong support from community and local institutions. Such actions are warranted regardless of climate concerns, but their solutions include ways to mitigate potential climate issues as well.

4.10.6 Conclusions

The disturbance of the global carbon, water, and nitrogen cycles through land use and fossil fuel combustion can strongly impact both natural and managed ecosystems. Impacts of climate in the coming decades, both positive and negative, depend on the specific ecosystem and the biophysical, social, economic, political, and cultural parameters. Warming, drying, and an increase of extreme weather events are examples of possible changes in regional and local climate statistics that could reduce food security, water security, and biodiversity and exacerbate soil degradation and desertification. These negative effects are exacerbated by the human dimensions such as population density, human resources capacity, local institutions, and political governance. Agroecosystems, covering 40–50% of Earth's land area, have the potential to both mitigate and adapt to climate. The mitigation potential exists through a large carbon sink capacity in soil and biomass, as well as the feedbacks produced by the crops' ability to alter reflectivity, change the fraction of heat transferred into the atmosphere by sensible and latent heat flux, and energy capture. The carbon sink capacity as well as energy mitigation can be realized through conversion to a judicious land use, restoration of degraded soils and desertified ecosystems, and adoption of recommended practices for soil, water, crops/plants, and animals management. Promotion of adaptive and coping strategies can be facilitated through payments for ecosystem services and adoption of climate-resilient agriculture. In this regard, the importance of local institutions and community involvement cannot be overemphasized. Recarbonization of the terrestrial biosphere is a win–win option because of its numerous cobenefits and cost-effectiveness of the natural process.
